Case 4 (No. 163712).—A man, aged 69, was admitted to the clinic, June 23, 1916. A diagnosis was made of a papilloma of the bladder the size of a hen's egg, lying in the right base. July 11, 1916, excision of the tumor and implantation of the right ureter was done. Papillary epithelioma was diagnosed pathologically. A cystoscopic examination, Oct. 27, 1917, one year and three and one-half months after operation showed no recurrence. The catheter passed easily up the right ureter and negative urine was collected. Phenolsulphonephthalein output showed 15 per cent. in the right ureter, and 17.5 per cent, in the bladder. The pyelogram showed the right kidney to be normal. The general condition of the patient was good (Fig. 25).

Case 5 (No. 185582).—A woman, aged 60, was admitted to the clinic, Feb. 13, 1917, and a diagnosis of carcinoma of the bladder was made. March 21, 1917, a suprapubic excision of one third of the wall of the bladder was done. One inch of the right ureter was removed and the left ureter was implanted into the base of the bladder. It was not possible satisfactorily to reconstruct the bladder. The involved portion of the urethra was removed also. Jan. 22, 1918, ten months after the operation, there was no evidence of recurrence of the tumor. The left meatus could not be seen; the right was normal. A catheter was passed well up the right ureter. The phenolsulphonephthalein output showed 12 per cent. in the right ureter, and a trace in the bladder in fifteen minutes. The left kidney was found to be functionless probably because of the tension on the ureter necessary for its implantation.

Case 6 (No. 69825).—A man, aged 54, was admitted to the clinic, June 27, 1912. A carcinoma of the left base and wall of the bladder was found. July 6, 1912, suprapubic resection of one third of the bladder with cautery of the base, and implantation of the left ureter was done. Cystoscopic examination, March 8, 1913, showed no evidence of recurrence. The left meatus spurted urine normally. In answer to an inquiry in August, 1916, the patient stated that he was in good health and had no urinary inconvenience.

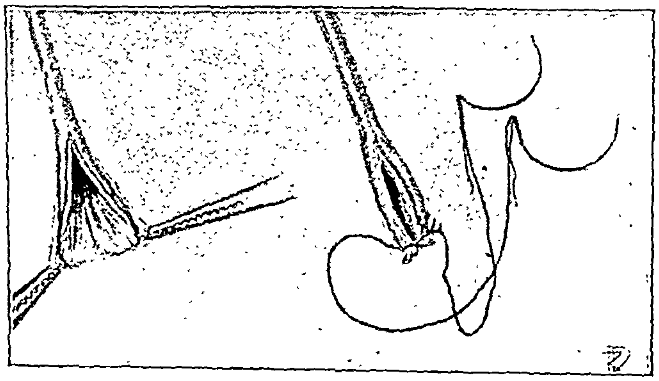

Fig. 9.—Preparation of the ureter for implantation into the bladder. Anterior wall split from one-fourth to one-half inch and anchoring sutures introduced.

Case 7 (No. 186610).—A man, aged 54, was admitted to the clinic, Feb. 23, 1917. March 9, 1917, a suprapubic resection of one third of the left wall of the bladder and one-half inch of the left ureter, with implantation of the ureter was done for carcinoma. Oct. 18, 1917, cystoscopic examination showed no recurrence. The left meatus was widely open and spurted urine normally. A catheter passed easily and the specimen of urine showed a few pus cells. Intravenous phenolsulphonephthalein appeared in four minutes, from the left ureter 4 per cent. and from the bladder 20 per cent. The catheter drained poorly. The pyelogram showed a normal kidney and ureter (Fig. 26). The patient's health is good.

Case 8 (No. 213632).—A man, aged 48, was admitted to the clinic, Nov. 20, 1917. A suprapubic excision with cautery was done at the base of the left wall of the bladder, and base of the left ureter for multiple papilloma. One large growth of the size of an orange was situated at the left meatus. Cystoscopic examination four months and twenty-two days after the operation showed no evidence of recurrence. The left meatus, which was located high up on the left wall of the bladder, was catheterized easily. Indigocarmin, dark blue in color, appeared in five minutes on both sides. The pyeloureterogram showed a normal pelvis and ureter throughout. Examination of urine from the left kidney was negative (Fig. 27). The patient has gained 8 pounds in weight and has no urinary inconvenience.

Case 9 (No. 213837.—A man, aged 42, was admitted to the clinic, Nov. 11, 1917. A diagnosis of a large tumor of the bladder and marked secondary anemia was made. The hemoglobin was 37 per cent. A transfusion of 500 c.c. of blood was given eleven days before operation. Nov. 24, 1917, a suprapubic resection of the left one third of the bladder, extending the dissection close to the right ureter, was done. The left ureter was implanted and a small rubber catheter was inserted into it for a short distance, and brought out through the suprapubic wound. March 22, 1918, four months after the operation, the patient returned for cystoscopic observation. There was no recurrence. The capacity of the bladder was 4 ounces. The left ureter had probably been implanted in the dome. It was gaping, and no excretion was seen. A catheter could not be passed. The right meatus, which was normal, was catheterized. Phenolsulphonephthalein showed 25 per cent. in the right ureter, and 2 per cent. in the bladder in fifteen minutes. The left kidney was functionless. The patient's general condition was much better. The hemoglobin was 58 per cent.

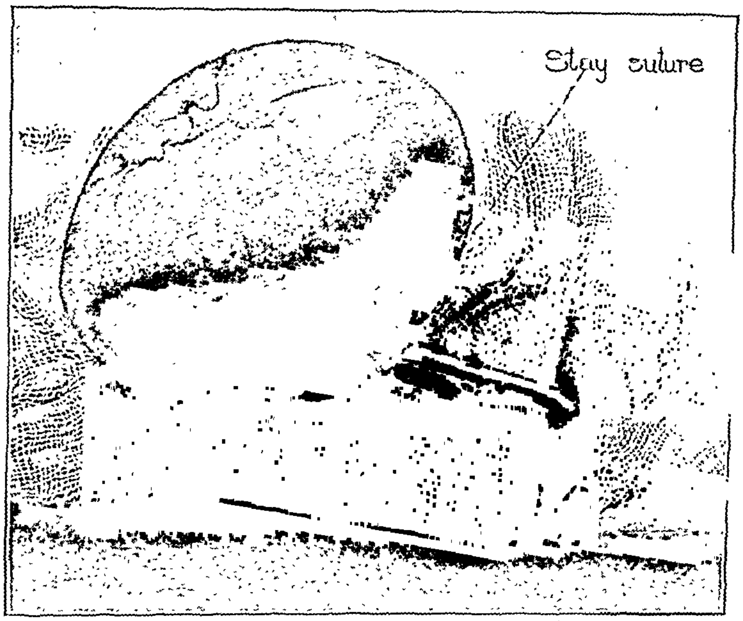

Fig. 10.—Showing tension of the stay suture when the bladder is distended.

Case 10 (No. 213710).—A man, aged 59, was admitted to the clinic, Nov. 13, 1917. November 24, resection of one third of the bladder, right wall and base, including two-thirds of an inch of the right ureter, with implantation of the right ureter was done. A small catheter was passed four inches up into the implanted ureter. The ureter was dilated considerably, apparently from obstruction, the result of the growth. Cystoscopic examination March 21, 1918, nearly four months after the resection, showed no recurrence. The right meatus was gaping. Contractions were absent and the left meatus was normal. Indigocarmin injected intravenously appeared from the left side in three minutes, dark blue in color. None was seen from the right meatus in fifteen minutes. The catheter could not be passed up the implanted ureter. The right kidney was functionless.

Case 11 (No. 204790).—A woman, aged 56, was admitted to the clinic, Aug. 15, 1917. The patient had complained of frequency of urination and hematuria for two months. Aug. 22, 1917, a suprapubic resection of one half the bladder and part of the vaginal wall with implantation of the left ureter was done. A diagnosis of epithelioma was made pathologically. Nov. 24, 1917, three months after the operation, there was no recurrence. The left meatus was not seen because of the deformity of the bladder. A Garceau catheter was passed into the right ureter. The phenolsulphonephthalein test showed 12.5 per cent. in the right ureter, and 17.5 per cent. in the bladder in fifteen minutes. The patient's general health is much improved.

Case 12 (No. 221950).—A woman, aged 33, was admitted to the clinic, Feb. 14, 1918. Following vaginal drainage for pelvic abscess, three years prior to admission, the patient developed incontinence. A left ureterovaginal fistula was found. Feb. 26, 1918, the lower eight inches of the left ureter was dissected out of very dense scar tissue and was reimplanted under tension. A small catheter was introduced into the implanted ureter and brought out through the urethra. A cystoscopic examination a month later showed granulation tissue in the left dome. No spurts of urine were seen from the left side. A Garceau catheter was passed into the right ureter, and the differential functional test showed 20 per cent. in the right ureter, and none in the bladder. The left kidney was functionless because of cicatricial contraction at the lower end of the left ureter.

Case 13 (No. 214196).—A woman, aged 23, was admitted to the clinic, Nov. 17, 1917. Following instrumental delivery fourteen months previously, the patient had developed incontinence. A diagnosis of left ureterovaginal fistula and right uretero-uterine fistula was made. The left ureter was implanted, Dec. 3, 1917, and the right was implanted, Dec. 22, 1917. A cystoscopic examination seven weeks after the first operation showed the left meatus to be normal. Indigocarmin appeared in five minutes, dark blue in color. A No. 6 catheter was passed easily. The pyelogram showed normal outline. A specimen of the urine contained a large number of pus cells. Inflammatory reaction obscured the right meatus. There was a small uretero-abdominal postoperative fistula on the right (Fig. 28).

Case 14 (No. 102891).—A woman, aged 41, was admitted to the clinic, March 24, 1914. The patient had developed a left ureterovaginal fistula following operation for cancer of the uterus five months previously. An implantation of the left ureter was done, April 7, 1914. Eighteen days later, a ureteral catheter was passed easily, and cloudy urine, showing numerous pus cells, flowed rapidly for twenty minutes. Two ounces of urine were withdrawn, the specific gravity being 1.001. Before implantation could be accomplished, the lower end of the ureter had to be dissected out of dense scar tissue.

Case 15 (No. 144658).—A woman, aged 42, was admitted to the clinic, Oct. 30, 1915. The patient had developed a right ureterovaginal fistula following hysterectomy done at the clinic. March 15, 1916, the right ureter was dissected free from the scar tissue and implanted into the bladder. A cystoscopic examination twenty days after the operation showed the end of the right ureter protruding into the bladder. It was not possible to catheterize on account of the obstruction. The left kidney was catheterized, and the differential functional test showed 13 per cent. in the left ureter, and 2 per cent. in the bladder in thirty minutes.

Case 16 (No. 163923).—A woman, aged 21, was admitted to the clinic, June 27, 1916. The patient had suffered from incontinence since childhood. The right ureter was found opening into the urethra. Implantation of a widely dilated right ureter was done, April 25, 1917. The cystoscopic examination four months later showed an infected hydronephrosis containing more than 2 ounces of cloudy urine. The phenolsulphonephthalein output showed 15 per cent. in the right ureter and 30 per cent. in the bladder in fifteen minutes.

Case 17 (No. 215976).—A man, aged 32, was admitted to the clinic, Dec. 7, 1917. An operation for diverticulum of the bladder was done, Feb. 26, 1918. The left ureter was found opening into this pouch and was transplanted. On cystoscopic examination six weeks later, it was impossible to get a satisfactory view of the transplanted meatus. A No. 6 catheter was passed into the right ureter and a differential functional test done which showed 25 per cent. from the right ureter, and 12 per cent. from the bladder.

Case 18 (No. 210877).—A man, aged 54, was admitted to the clinic, Oct. 15, 1917. Nov. 16, 1917, a suprapubic resection of one half of the bladder with implantation of the left ureter was done for cancer. The patient died in the hospital on the fourth day after the operation. Necropsy showed advanced myocardial changes and pulmonary edema. There were multiple small cortical abscesses in the left kidney and a slight hydronephrosis. The ureter was contracted at the site of the anastomosis and was dilated above this point (Fig. 29).

Case 19 (No. 218877).—A man, aged 60, was admitted to the clinic, Jan. 12, 1918. Jan. 19, 1918, a suprapubic resection of the bladder and one and one-half inches of the right ureter, with reimplantation into the dome of the remaining portion of the bladder, was done for extensive cancer. A small catheter was passed into the implanted ureter and brought out through the suprapubic wound. The patient died on the twelfth day from bilateral pulmonary emboli. There was no obstruction at the site of implantation. Both kidneys showed arteriosclerotic changes with slight dilatation of the right kidney pelvis (Fig. 30).

Case 20 (No 101710).—A man, aged 45, was admitted to the clinic, Mar. 11, 1914. A part of the right wall and base of the bladder was excised, Dec. 14, 1917, with implantation of the right ureter into the base, for early epithelioma of the bladder. A small catheter was passed into the implanted ureter. The convalescence was uneventful for one month, when abdominal distention and coma developed, and the patient died. Necropsy showed a general peritonitis, with firm union of the implanted ureter and an old perivesical hematoma near the site of implantation (Fig 31).

Case 21 (No. 219087).—A man, aged 40, was admitted to the clinic, Jan. 14, 1918. Jan. 22, 1918, a resection of the base and the right one half of the bladder, with transplantation of the right ureter into the dome was done for extensive cancer. The ureter was dilated to the size of a finger. A catheter was passed into the ureter. The cancer had extended into the perivesical fat. The patient died two months after the operation. Necropsy showed a large bilateral psoas abscess, extensive metastasis to the liver, and carcinomatous extension into the perivesical area with marked sloughing of tissues. The site of anastomosis could not be made out, on account of the necrosis of the bladder, and the surrounding infiltration. There was marked bilateral dilatation of the ureters and kidneys (Fig. 32).

ABSTRACT OF DISCUSSION

Dr. V. D. Lespinasse, Chicago: The specimen that interested me most was the one which showed a dilatation of the ureter without dilatation of the kidney pelvis. In my work with dilatation of the ureter for the removal of stone, we found that when the ureter is obstructed a dilatation begins at that point and travels toward the kidney pelvis. These specimens show this phenomenon beautifully, and one in particular with a slight cicatricial contraction and consequent partial obstruction shows the dilatation progressing up to the kidney. The dilatation had just started to involve the kidney when the animal was sacrificed.

Dr. Arthur L. Chute, Boston: I would like to call attention to two things. One is a sort of rough and ready method of replanting or transplanting the ureter which I have used in quite a number of dogs. I introduce from below in either a man or a woman a long uro-catheter of size 12, making a little hole in the bladder anywhere that I can do it, and after I have slipped the ureter up 3 or 4 c.c., I then push the whole thing back into the bladder, and insert one or two stay sutures wherever I can get them. While it is not a very attractive technic it brings the result. I have not had any opportunity of catheterizing human ureters in that way, but on dogs it seems to be a very feasible method. At the same time, with a retention catheter you keep the bladder open and prevent the possibility of pulling out, while it does not add very much to the extent of the operation.

Dr. Charles M. McKenna, Chicago: I can see from Dr. Peterson's slides that surgical repair is the important point which he intended to bring out. Too much cannot be said about surgical repair, either in genito-urinary surgery, or in general surgery. I do not quite understand why Dr. Peterson makes a second incision in the bladder to do the transplant. I should like to ask Dr. Peterson why it is not a good plan to transplant the ureter in the upper angle of the original incision. There will be less scar tissue to deal with there than there will by making a new opening, and less danger of infection since you have only one incision. I have used this latter method in my own cases and am satisfied with the result.

Dr. Bernard Erdman, Indianapolis: What method of transplantation was used in the case of the bladder with one ureter, and one ureter transplanted into the bowel?

Dr. Anders Peterson: The Coffey technic was used for the bowel implantation and the Stiles technic for the implantation into the bladder.

Dr. F. C. Herrick, Cleveland: I think in the anastomoses which possibly may be in question, and also in preventing possible stricture from the swelling, a catheter is of very great value to be left in for from five to eight days—possibly seven days—and then bring it out. It comes out very readily, of course. Some use a solid bougie.

Dr. Anders Peterson, Rochester, Minn.: Dr. Chute has repeatedly placed in the ureters a small rubber catheter large enough to completely fill the ureter. It is brought out through the suprapubic wound that is used as drainage after the section, and drains the urine quite freely. We believe it is a good thing to do; but in animal experiments, of course, it is not feasible, and it does not seem to be necessary, since results may be obtained by careful methods of suturing. In man there is danger of stricture.

In answer to Dr. McKenna's question in regard to making the anastomosis in the upper angle of the incision. This can, and very often has been done. In operating on the bladder large resections have to be made. The method used is not of such great importance, but all efforts must be made not to damage the upper section of the ureter which you are going to use. The ureter does not stand manipulation. If that is borne in mind, I believe results may be obtained without catheters.

Pellagra.—Figures covering the death rate for pellagra in the United States among the policy holders of the Metropolitan Life Insurance Company showed a gratifying decrease during 1916. In 1911, according to a bulletin issued by the company, there were 277 deaths among its policyholders from pellagra; in 1915 the number had increased to 650, and the rate had increased from 3.6 per hundred thousand exposed persons to 6.7. In 1916 the deaths fell to 368, and the rate to 3.6 as in 1911, a drop of 46 per cent. in 1916 as compared with 1915. This drop was observed in many districts of the South where the company does business. It is suggested that the drop in the death rate from this disease coinciding with the greater prosperity of the agricultural portion of the South during the high prices incident to the war in a way confirms the tentative conclusion of some of the government experts that pellagra is a "deficiency" disease induced by insufficient, poorly balanced dietaries rather than an infectious disease. The statistics of the company further show that the disease is more prevalent among the colored than the white people, and more frequent in women than in men. It is also indicated that the incidence of the disease increases with age.

THE END-RESULTS OF OPERATIONS FOR CANCER OF THE RECTUM

WITH SUGGESTIONS FOR IMPROVING THEM *

J. RAWSON PENNINGTON, M.D.
CHICAGO

The sole plan at present which offers any hope of cure of cancer, though often only temporary, is the knife.

Radium is of little avail in columnar-celled growths, that variety of malignant disease which principally affects the lower bowel. Morson[1] states that while we may expect retardation of the neoplasm and relief of pain, irradiation is often followed by fibrous stricture, especially if the exposure has been for more than twenty hours, and he strongly advocates colostomy before treatment with radium is carried out.

In 1913, 1914 and 1915, of fifty-one patients treated at the Radium Institute,[2] London, thirty-three improved, ten did not, and eight died; while fourteen more abandoned treatment, probably on account of not obtaining any relief. The latest results were not very brilliant either. In 1917, they "were not constant or uniform, but in some instances growths regarded as inoperable were so much improved . . . that they were removed and the patients remained free from recurrence. This, however, has not frequently happened, and in the majority of cases the most that can be hoped for is healing of ulceration, diminution of the rate of growing, checking of the hemorrhage and postponement of the date at which colostomy becomes imperative." In fairness, though, it must be stated that it is a rigid rule there to treat inoperable cases only, or cases in which the patients absolutely refuse intervention.

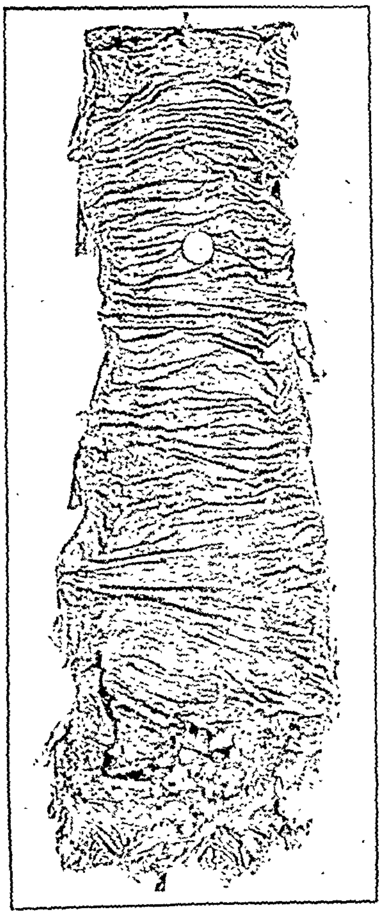

Fig. 1.—Photograph of specimen removed by author. Cancer mass in anorectal region. Circular dot shows metastatic lymph node 10½ inches above anus.

At the Manchester Radium Institute, Burrows and Luyton[3] also found: "The improvement in cancer of the rectum was merely temporary."

On the other hand, Janeway[4] states that both the anal as well as the rectal carcinomas, especially the latter, have shown a marked susceptibility to radioactivity. This statement is based on very insufficient evidence, it seems to me, for of thirty-four patients treated, two at the time of report showed no evidence of the disease, fourteen were improved and eighteen were unimproved.

OPERABLE AND INOPERABLE CASES, AND MORTALITY

The operative mortality is high. As a rule, when patients are first seen, the disease is so far advanced that extensive dissections are necessary. Hence there is considerable shock. Another important factor is sepsis; and Mayo places it at 39.8 per cent. Mummery[5] of London, however, believes that with careful technic this should be avoided, and states he lost but one case in the previous three years, though but a year or so before he gave as his opinion that 90 per cent. of deaths following excision of the rectum "are due directly or indirectly to sepsis."

Hartmann[6] collected for the "low" operation (that is, the perineal and sacral methods) statistics from seventeen clinics besides his own, a total of 1,665 operations with 264 deaths, or 15.8 per cent. In addition to his figures (260 cases) for the combined operation, I have gathered enough to bring the total up to 320 operations, with 129 deaths. While a few cases from the Mayo Clinic are included in the series, we learn from more recent papers by W. J. Mayo,[7] that the total is now much larger. Up to Dec. 31, 1915, of 753 patients, radical operation was done in 430 cases, with an operative mortality of 15.5 per cent. Before 1910 it was 17.8, and remained about the same, 17 per cent., for the next three years, but for the period from 1913 to 1915, it was reduced to 12.5 per cent.—a splendid showing. Within the last few weeks, Lynch[8] informs us that the mortality for his and Tuttle's cases was 16 per cent.

The proportion of cases judged suitable for operation, the operability in other words, has been steadily rising in that great center of surgical activity, the Mayo Clinic. From 1910 to 1913, it was 51 per cent., and in the period from 1913 to 1915 it was raised to 71.8, though, as just stated, the operative mortality fell from 17.8 to 12.5 per cent. Even so experienced a surgeon in rectal surgery as Mr. Cripps[9] performed excision in only 108 cases of 445, or 25 per cent., 151 patients being subjected to colostomy, and 115 to palliative operations. In Tuttle and Lynch's experience during nineteen years, 153 out of 491 cases were deemed inoperable.

Extension of the cancerous process to the contiguous structures was, until recently, held to place the case in the inoperable class, but this no longer holds good for the Mayos. In six cases total hysterectomy was performed. In six more, a part of the posterior vesical wall was resected. The similar wall of the vagina was removed in twelve, and the whole of the prostate, or part only, with one or both seminal vesicles was removed in two, while on five occasions, one or more loops of small bowel as well were resected. As long ago as 1905, Mackenrodt[10] showed that the parametrium and vagina are often invaded, and he excised them with the uterus itself, when necessary.

Not long ago, a three-year survival following operation for malignant disease was looked on as a suc-

cessful result. Of course, this is no longer deemed a "cure," and even the three-year survivals in cancer of the rectum are not especially notable from a numerical standpoint. I have collected 966 records of operations, 218 of these being three-year survivals. In addition to those of Tuttle and Lynch, they are from the clinics of Roux,[11] Kocher,[12] von Eiselsberg,[13] and Hochenegg respectively. At the Mayo Clinic, of 364 patients, 37.8 per cent. lived three years or more, and 35.8 per cent., five years or more.

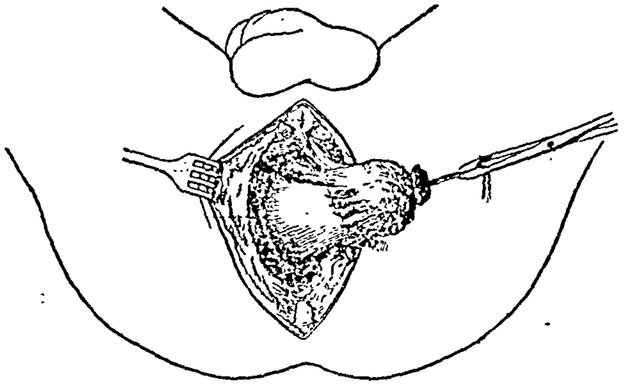

Fig. 2.—Removal of rectum by perineal route, showing impossibility of getting high enough up to reach lymph nodes (Quénu and Hartmann). The middle fasciculi of the levator have been divided, exposing the lateral surface of rectum, and in front the anterior fasciculi of the levator.

TYPE OF OPERATIONS

The perineal operation of Lisfranc (1826) now nearly a century old, strange as it may seem, occasionally furnished results as good as those obtained by more extensive procedures. Thus the late Mr. Dent[14] of London, Nov. 9, 1882, operated on a man, aged 52, by the perineal route. The nodes were removed from the ischiorectal fossa, the anus being left. The bowel could not be pulled down. As a result, there was good control of solid feces and partial of fluid feces. Jan. 29, 1904, the man was readmitted. The anus, which appeared perfectly healthy, was represented by a funnel-shaped depression. The point of union of the divided intestine was a sphincter-like constriction which admitted the index rather easily. Evidences were present of metastases to the liver, and the patient died, April 25.

Of fifty-eight operations done by Miles[15] there was recurrence in fifty-five, and other things being equal, this route should be restricted for epitheliomas limited to the anal region.

Notwithstanding the unfavorable opinion respecting it entertained by many authors, Kraske's plan of sacral resection, judging by the figures from Hochenegg's clinic furnished by Bacharach,[16] gives good results, namely, about 320 operations, with an operative mortality of 13.7 per cent. In 1,244 cases collected by Lusk[17] from fourteen different continental clinics, the operative mortality varied from 6.4 (Poppert) to 32 per cent. (von Bergmann, Schede and Rotter, respectively).

Nevertheless, the method of choice is the combined or abdominoperineal route, which alone affords free access and enables the surgeon to go well beyond the tumor mass, excising it with any extension to the regional nodes, and allowing the arteries to be ligated at a point where there is no danger of gangrene.

In regard to metastases, in the enormous number of necropsies on carcinoma in various parts of the body tabulated by the lamented Murphy,[18] that is, 10,310, nearly 20 per cent. (or 19.7 to be exact) had no metastases. The proportion for the rectum separately was about the same (22.2 per cent). This accords with the usual experience that the types of cancer involving the rectum and anus — squamous and columnar-celled—frequently end fatally without any evidence of metastatic deposits.

Last year, Symmers[19] studied a series of 298 metastases found in 5,155 necropsies at Bellevue Hospital in a decade, and observed that of the twenty-eight examples of carcinoma in the lower intestinal tract, no less than 15, or 53.5 per cent., were free from secondary growths. A striking contrast to the high degree of malignancy attending tumors of the upper bowel and stomach.

I have collected 997 necropsies on cancer of the rectum, and in about one third (324 cases) the regional nodes were affected. They would be beyond reach, as a rule, by the perineal or Kraske operations.

ABDOMINOPERINEAL OPERATION

To prevent cancerous material being forced into and along the lymphatics at the time of operation, it is a well recognized procedure in cancer of the mamma, for example, to begin the dissection from above and work down against the lymph current; and the same should hold good in excision of the rectum. Obviously this can be done only by the abdominoperineal route.

In regard to the distribution of the lymph vessels, for the present purpose and without going into detail this may be stated as ending in the inguinal nodes for the perianal collectors, and in the nodes of the mesosigmoid for the collectors from the rectum proper. Here again the latter would be out of reach in many instances if sought for by the "low" operation.

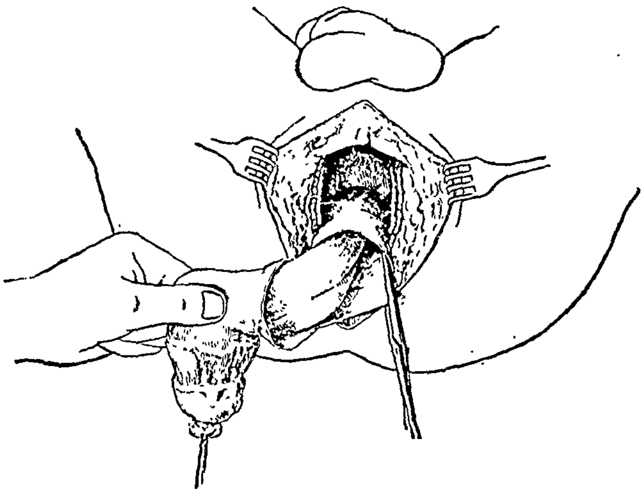

Fig. 3.—Same as Figure 2 (Quénu and Hartmann). Between the forceps and the wall of the rectum, which has been pulled to the right, is seen the left layer of the mesosigmoid forming a triangle, the anterior base of which is a free border.

A frequent cause of death following operations by the perineal or sacral method is gangrene of the bowel, either partial or complete. This is due to the fact that the superior hemorrhoidal arteries are end-arteries as shown by Sudeck[20] in 1907 and corroborated by Hartmann[6] in 1909. The "critical point" of the former is at the junction of the superior hemorrhoidal with the lowest large anastomotic branch. When ligation is performed below this point, gangrene will probably follow, since the bowel does not receive adequate nourishment. Moreover, to get sufficiently high up to deal with this junction, one must go in from above. Hence, Sudeck suggested an intervention in two stages: 1. Through a laparotomy incision, the superior hemorrhoidal is ligated high up, and at the same time the bowel is partially loosened. Then, 2, the resection is completed by way of the perineum.

On two occasions, Hartmann, after bringing the bowel down through a perineal operation, found that gangrene had ensued; and in several others, while there was an apparently perfect operative cure, recurrence took place in the pelvic cellular tissue, although the mucosa itself remained free. Both the former instances concerned patients in whom it was necessary to divide the hemorrhoidal vessels rather high up, either because the carcinoma involved the upper ampulla, or because the tumor, though low down, had infiltrated the mesosigmoid. In such cases, he observed, once the rectovesical pouch is opened, it is not rare to find the rectosigmoid junction presenting and easily pulled down, while the rectum itself, and particularly its ampulla, remains fixed, held solidly by the superior hemorrhoidal arteries, which come down from the aorta almost in a straight line. Therefore these vessels must be divided in order to bring the rectum down, and while this enables the bowel to be pulled out, gangrene is apt to follow. This complication is readily understood by a study of the vascular relations. In other portions of the bowel, the arterial supply is by a series of anastomosing arches, while in the terminal portion, the hemorrhoidal arteries descend without giving off any anastomoses.

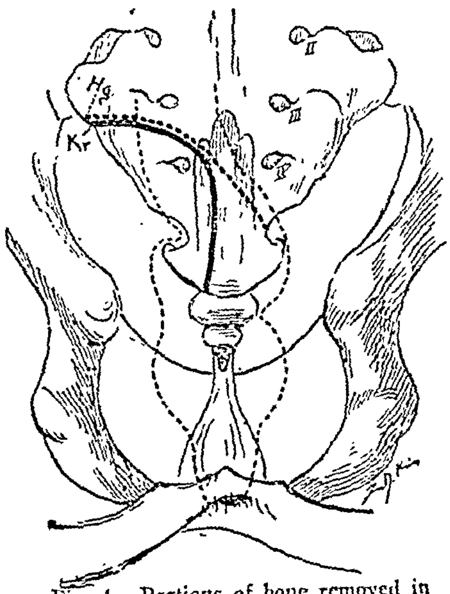

Fig. 4.—Portions of bone removed in Kraske method; also showing impossibility of getting high enough up to reach nodes (Quénu and Hartmann). Continuous line, Kraske's line for dividing bone; dotted line, Hochenegg's line.

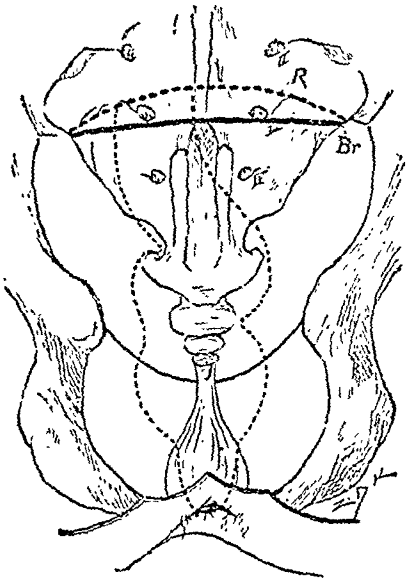

Fig. 5.—Same as Figure 4 (Quénu and Hartmann). Continuous line, Bardenheuer's line for dividing bone; dotted line, Rose's line.

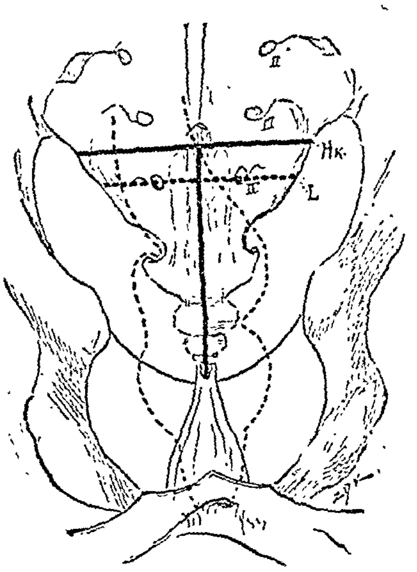

Fig. 6.—Same as Figures 4 and 5 (Quénu and Hartmann). Continuous line, Heinecke's line for dividing bone; dotted line, Levy's line.

This arrangement is shown by a series of injections carried out by de Dieterichs under Hartmann's direction. The former found: 1. Ligation of the inferior mesenteric had no effect on the circulation of the rectum, provided it was done between its origin and the last important collateral, which comes off two-fifths or three-fifths inch below the sacral promontory. 2. Ligation of the inferior mesenteric below this lowest collateral leads to almost complete suppression of the blood supply to the rectum and to the rectosigmoid junction. This suppression is all the more complete in that, during perineal amputation, the inferior portion of the bowel, being isolated from its peripheral connections, the branches of the middle hemorrhoidal as well are severed. 3. Ligation of the superior hemorrhoidal, right and left, shuts off the circulation in the corresponding sides of the bowel. After ligating above the last anastomotic arch, it is important to tie both ends of the vessel. By neglecting this precaution, Hartmann lost a case from hemorrhage at the lower end.

Hartmann's experience leads him to corroborate Sudeck's advice to perform a two-stage operation. In the first, in addition to ligating the vessels, one is able to clean out the presacral tissues, lymph nodes, etc., which may be invaded by the cancerous process. The second stage is excision through the perineum.

It seems to me no better argument for the combined operation may be made than the two cases referred to by Cole[21]: In one there was a deposit in the pericolic connective tissues 3 inches above the margin of the rectal growth, and he points out that if the latter had been excised together with one inch of normal bowel above, the line of incision would have passed close to the other deposit. In the other, a malignant ulcer was present on the posterior wall, and though small (0.75 inch wide), microscopic examination showed it had involved the whole thickness of the wall and spread freely into the connective tissue and nodes of the mesocolon.

Another argument for the abdominoperineal method is that the growth in the rectum may be secondary to one higher up, and the latter escape detection. Cole also narrates an example of this. At a laparotomy, the pelvic colon was found adherent to the anterior wall of the rectum at the bottom of Douglas'

---

culdesac. It was thought unsafe to separate the uterus, so this organ as well was removed. Some 12 inches of bowel were excised and two growths found present, though only one had been diagnosed; both were in the bowel wall at the site of adhesions. The upper in the pelvic colon, of the whipcord type, had completely encircled the intestine, producing the symptoms of obstruction for which the patient sought advice. The lower growth in the rectum was a carcinomatous ulcer, affecting the anterior and left lateral walls. Cole found it difficult to escape the conclusion that the upper mass was the older, and that the lower one arose from contact.

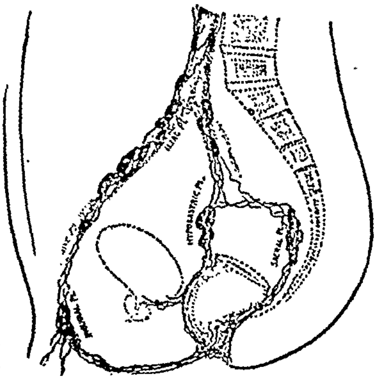

Fig. 7.—Lymphatics of rectum (Barnes). The lymphatics, as a rule, flow in the direction of the blood vessels. An exception is found in the lymphatics around the anus, which flow into the inguinal nodes.

Another reason for adopting the combined method is that the growth in the rectum may be secondary to one higher up, a "graft," in other words. This variety generally follows a tumor in the stomach, though it may also be due to one in the ovary, gallbladder, or the intestines, especially the larger one (Oehler[22]). Out of 463 cases, secondary nodules were found in the rectum in fifteen. In six isolated nodules above the growth, five below the mass, and in four multiple secondary nodules (Colwell and Woodman[23]) were found. Laparotomy allows search for the other one to be made.

Attention may be here drawn to some interesting findings some years ago, of Ryall[24] and Moullin.[25] The former, who is surgeon to the London Cancer Hospital, reported twenty-five examples of what he calls "infection" of operative scars after cancer operations; these involved all parts of the body. I have time, however, to quote only one or two:

> In a woman, aged 32, an exploratory operation was done for cancer of the upper rectum, which proved inoperable. Some time later she was readmitted and colostomy done. At this time, it was noted that a series of nodules were present in the laparotomy scar, and they all appeared to have arisen in the site of the sutures. A similar case is narrated in a woman, aged 26, with cancer of the sigmoid.

Ryall states:

> Cancerous infection of wounds during operation is a real and exceedingly grave danger, and one which I regard of the utmost importance. Moreover, it is a danger that cannot be too carefully guarded against, and any failure to avoid it has an important bearing on cancer recurrence.

The following year, Moullin recorded a most interesting case from this standpoint:

> In a man, aged 48, at operation for pyloric cancer, some disseminated nodules were found scattered over the gastric serosa. Gastro-enterostomy was done. Six months later, there was a double row of cancer nodules on either side of the laparotomy wound. Two rows of sutures had been inserted, one interrupted, of stout catgut, passing through all the layers of the wall, except the skin; the other continuous, of fine gut, through skin only. Practically all the former points, though none of the continuous ones, were infected. It was evident cancer cells from the peritoneal cavity had invaded the wall wherever the parietal peritoneum had been pierced by a suture. The stitches had not carried the cancer germs in, for they had never been near the growth. But either by perforating the serous layer or by acting as irritants, they had helped the development of the invading germs to such an extent that each suture point had become a cancerous nodule. The immediate source of the infection, Moullin thought, was in all probability the nodules on the serosa, which were constantly rubbing against the anterior wall. The line of the laparotomy incision seemed intact between the two rows of nodules.

The same explanation holds good for cases in which cancer recurs at suture points in cancer of the mamma. Moullin points out that the cancer germs are not carried in by the needle or suture, but they are more widely distributed in the surrounding tissues than is apparent at the time, and only develop or perhaps develop first at those points where the resistance of the tissues is lowered by the presence of an irritant, such as a suture.

If, as our author believes, the germs are more widely distributed than seems to be the case, is not this additional argument for a wide excision, which can best be done with a free exposure of the parts, such as is only to be had by abdominal section?

CONCLUSION

I would repeat the suggestion I made several years ago, in a paper read before the American Proctologic Society,[26] which I believe still holds good. First of all, every person who has reached the so-called "cancerous age" should be examined periodically for evidence of commencing carcinoma, not necessarily of the rectum alone, but, in women for example, of the uterus and mamma also. Neither the patient nor the practitioner should allow his interest in these periodic examinations to slacken. In my paper, I refer to an instance in which such examinations were made at regular intervals after excision of a mammary carcinoma, and eighteen years elapsed before the search was rewarded by discovery of a recurrence in the scar.

The responsibility of the family physician is great, for he is usually the first one to be consulted. He must not content himself with a perfunctory diagnosis of "piles" without even inspecting the the anal region, and an equally perfunctory prescription of ointments.

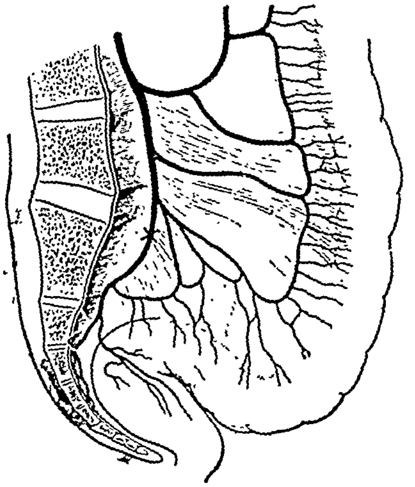

Fig. 8.—Blood supply of the mesosigmoid (Hartmann). The cross shows the location of the "critical point."

Jones[27] states that of the patients entering the Massachusetts General Hospital with cancer of the rectum, 75 per cent. had been treated for a longer or shorter time for "hemorrhoid," and the remainder for

"diarrhea." Instead, the bowel must be inspected through the proctoscope. This calls for possession of the necessary armamentarium, and in turn the skill to interpret appearances visible through the instrument. In case of doubt, life should not be jeopardized by a procrastinating policy, but advantage taken of consultation with the specialist.

It has been shown of late years that a large proportion of malignant growths originate in scar tissue. Patients with rectal cancer often give a history of previous operations on the bowel. Does the cancer occur in the cicatricial tissue left from an operation done by one of the usual methods—ligature, clamp and cautery, or some other technic leaving much scar tissue, and sometimes stricture? May it not be occasionally grafted on the scar remaining after the common incision plan of operating for fistula? I have recently had such a case. All proctologists have seen large and ugly scars from time to time following this method. Here is a suggestion to be followed: Secure smooth healing by resorting only to such procedures as leave a minimum of cicatricial tissue, and consequently the least possible nidus for future mischief.

ABSTRACT OF DISCCUSSION

Dr. Dwight Henderson Murray, Syracuse, N. Y.: I hope that when Dr. Pennington sums up he will tell us what determines the operability of a cancer, and at what point in the life of it, or what part of the extension of it. In my opinion, it is very difficult, even with the microscope and a good pathologist, to tell just where cancer tissue ends and normal tissue begins. Even beyond the point in the tissues where the microscope shows that changes have taken place, the tissues have really changed, and the microscope will not show it. My own experience forces me to the conclusion that in the majority of rectal cancer patients, if we will do a colostomy it will be a greater kindness to the patient than to try to extirpate the cancer by operation. The majority of these patients will live about as long as the operated ones.

Dr. William M. Beach, Pittsburgh: It is exceedingly hard to believe many of the reports of end results in cancer of the rectum. The end results of my cases, and I have had over a hundred in the last ten years, is death. In the cases in which I operated, the longest period of life following operation was three years; and yet, while I am rather pessimistic of end results, I feel that there are certain cases in which we should intervene operatively. Now what are one or two of the signs that will lead us to select a case for operation? One is the hemoglobin percentage. If the patient has 45 or 50 per cent. hemoglobin, do not operate; if the hemoglobin percentage is nearly normal, 70 or 80 per cent., it offers a fair chance of success. The next point that will guide us in the selection of an operative case is the location of the neoplasm. If it is located low down, it offers the best chance for operation; if it is located in the loop of the sigmoid, it offers a fair chance. In operating in such a case we should resort to anociassociation. Many of these patients die from shock. Anociassociation helps wonderfully in tiding the patient over the crisis of the operation. Cure of cancer of the rectum, as spoken of by men who report cures, I believe, is a relative term. Very often they do not state the length of time the patient lives. If there is no recurrence, say after a year, it is reported cured. A surgeon near my city reported a case of absolute cure of cancer of the rectum, and it was cited far and wide. The patient was said to have lived out his natural life. I asked the surgeon whether he was sure of his diagnosis and he admitted that he was not. I believe that it was a case of syphilitic stricture. So that in reporting these optimistic results, the diagnosis should be positive. I operate on some of these patients, for I believe that if you can give a patient one year or two years or three years of life, that is much more comfortable than if you do not intervene. I never cured a case, and I never heard of anybody else that did. I agree with Dr. Murray, that we should do the more rational thing, a colostomy, and then, if possible, apply radium. In a number of cases I tried following up a colostomy with radium. One patient is still living, after two years. He is not cured. Radium could readily be applied because the lumen of the rectum was not interfered with much. It was full of cancer nodules, and the radium is simply inhibiting the process of the growth. These patients are all anemic, and for that reason the powers of resistance are very low; hence a great deal of shock is connected with the operation.

Dr. Charles J. Drueck, Chicago: Dr. Pennington deserves a great deal of credit for teaching patients to come to us in the precancer stage, yet I have not seen any results from his efforts. Most all of these patients come when the cancer is well advanced. Such patients must have something done for them. In a case of almost complete obstruction, I made an abdominal anus, and the patient is still living, a year and a half or more after operation. He is in very good physical condition. Although these patients come to us when they are anemic, still, after the abdominal anus is made, it is sometimes surprising how they will rebound. They regain almost, if not quite, all their former vigor. In the second stage of the combined abdominoperineal operation, when we do the perineal work, I think we are inclined to be urged by the patient to do the perineal section too soon. I have one case in which the combined operation was done, and the patient is alive, without any recurrence, over two years after operation. If we can tide these patients over and not submit to the second stage of the operation until they have rebounded as much as they are going to, I think we can get better results from our perineal work.

Dr. George E. Pfahler, Philadelphia: It has been shown that you can get a great deal of information in diagnosis, actual demonstration of the disease and locating the extent of it, by a careful roentgen study. Dr. Pennington dismissed the subject of roentgen therapy and radium therapy by mere mention. Now he is probably justified in doing that if it is a question of replacing the operation by the roentgen therapy or radium therapy, but there is no reason why all three cannot be used, or why they should not be used in every case. Operate if you can. Do all you can by operation. Use radium locally, and use deep roentgen therapy through the whole field of glandular extension that is likely to be involved, and I am sure that you will improve the results. Statistically, no one can say just how much can be done, because there have not been a sufficient number of these cases treated. I have treated only a few, because only a few cases have been left to me for postoperative treatment. Why this is I do not know. Those that have been left have given encouraging results generally, and the patients that have been left to me for treatment are those far beyond any operation. While I have obtained some improvement, some palliation even, in those cases, I have never had a patient I considered well. I have seen many convincing results of the disappearance of recurrent cancer. If you will just combine this additional force to what you are doing by surgery, and then introduce radium against the growth, thoroughly filtered, especially by the nonmetallic substance, and then use crossfire deep roentgen therapy, I am sure you will accomplish more than in any other way.

Dr. J. Rawson Pennington, Chicago: Formerly I used the roentgen ray in the treatment of cancer of the rectum. For the first few days the patients seemed to be greatly benefited, but later the disease appeared to advance more rapidly than if I had not used it. However, our knowledge of this agent today is in advance of what it was years ago. Concerning Dr. Murray's query, I cited the statistics of the Mayo Clinic. Do not think I am overoptimistic about curing cancer of the rectum. I am not; but one thing is very certain —if in 22 per cent. of the cases of cancer of the rectum the tumor is a local disease, we should cure a larger percentage than we do. The method of procedure has much to do with the end results. Among the various operations for cancer of the rectum, the radical abdominoperineal operation with left inguinal colostomy is the one most likely to eradicate the disease. It cannot be denied that by this procedure the operator has the best opportunity to circumvent the disease, and is less likely to squeeze the infected material into the surrounding tissues.

Dr. Dwight Henderson Murray, Syracuse: Dr. Pennington did not answer my question. I want to know what the physical findings are, and what the condition of the parts is that will show when a case is operable, and when it is not. I do not care anything about the statistics. A certain number of patients are operated on and a certain number are not, but when you examine a case, on what do you base your decision of operability?

Dr. Pennington: That question is decided on the physical findings. If the patient is very anemic, past 70 years of age, has much albumin in the urine, nodules in the liver, and other evidences of metastases, or if the condition of his heart is such as to question the advisability of giving an anesthetic, advise against an operation. If his condition is good, he is under 70, with little or no albumin in the urine, no recognized evidences of general spread or glandular enlargement, and the condition of the heart fairly good, operate.

Dr. Murray: Suppose ten or even twenty out of a hundred get "well" for two or three years, as a result of operation, and that thirty out of a hundred die a year and a half or two years earlier because of the operation, what about that? How much is to be gained as the result of the operation?

Dr. Pennington: No man knows, nor can he foretell, the natural termination of human life.

TREATMENT OF COLON BACILLUS INFECTIONS OF KIDNEY AND BLADDER

BY SURGICAL MEASURES APPLIED TO THE ASCENDING COLON *

GRANVILLE MacGOWAN, M.D.
LOS ANGELES

My frequent observation has been that colon bacillus infections of the kidneys and the bladder persisting and unyielding to treatment are invariably due to colonic stasis of the fecal current. This interruption is usually in the cecum and is due to adhesions of this organ to the surrounding structures immobilizing it. From the chronic stasis thereby induced, a constant supply of colon bacilli enter the circulation through the lymphatics in the kidney capsule or by the blood stream and primarily infect the kidney pelves on their way out, if there is any interruption to the free exit of urine, either in the ureters, at the neck of the bladder, or in the urethra. Once the infection is established, it is practically incurable until a normal condition in the large intestine or one approximately normal is restored by surgical measures.

REPORT OF CASES

Case 1.—G. J., aged 46, railway engineer, Sept. 18, 1916, complained of prostatic trouble. Urine freshly passed into a sterile glass contained many motile bacilli and much pus. Material massaged from the prostate did not contain any pus or residual urine. The image of the bladder neck was normal. There were a few recent hemorrhagic spots on the superior bladder wall and two on the right lower wall, probably made by my assistant with the catheter. There was a mild cystitis of the bladder base. Polypi were visible in the posterior urethra. The patient gave a history of sexual strain. His condition was thought to be chargeable to these polypi, and they were removed in several sittings, with the electric cautery and silver nitrate fused on a probe. The bladder was irrigated daily with mixed potassium permanganate and silver nitrate solution. October 5, the urine having become clear, the patient went back to work, but on the 18th of the same month, he came again with his urine very cloudy with pus and colon bacilli, and complained of slight pain in the right costovertebral triangle. He was treated in the same manner until November 20, when the urine was again perfectly clear and the prostate normal. He was then sent away, but returned, Jan. 4, 1917, complaining of pain in both sides in the neighborhood of the kidneys and with the urine loaded with colon bacilli and containing many pus corpuscles. Cystoscopy was again performed and the right ureter catheterized. This urine contained many colon bacilli, no pus, a few blood corpuscles and many epithelial cells, both small and large, some with fatty degeneration. Six c.c. of thorium solution were introduced and a pyelogram taken which was negative as to stone or to deformity of the kidney pelvis. On the 7th, the urine was macroscopically clear, but on the 8th, after a long automobile ride, it contained much pus and clouds of colon bacilli. On the 27th, the urine was clear again, and as the patient was feeling excellent he was sent back to work. In the interval between January 4 and January 27, he had pelvic lavage and treatment for the bladder and prostate with all the usual means for combating colon bacilli, including vaccines and the various balsams. I determined that if the disease recurred I would examine the intestine by the roentgen ray. When the patient returned, February 27, this was done. The plates showed intestinal stasis about the appendix and cecum, and the screen showed this part of the intestine to be immovable, containing barium more than forty-eight hours after ingestion of the meal.

March 30, after the bowels had been well emptied with castor oil and black draft for several days, Dr. Henry Howard and I performed a laparotomy. We found the omentum adherent to the top of the bladder, and also, in two places, to the anterior abdominal wall; the cecum was bound to the ileum and the side wall of the abdomen and doubled over in such a manner as to adhere to the ascending and transverse colon. The appendix was atrophied but unusually long and with its apex adherent to the liver; it was removed and the adhesions broken up. As much of the raw surface as was possible was covered with peritoneum and omental patches. About three weeks after his operation, the patient had great showers of calcium phosphate, followed by one of urates, mixed with indigo, which could be seen as a dark powder in the urine, the urate crystals were very abundant and sparkled like topazes when the urine stood in the sunlight.

Before he had entirely convalesced from his operation, the colon bacillus infection had disappeared from the urine and it has never returned. The chronic constipation has never been entirely corrected, but by the use of oxgall tablets and agar agar, he has been able to prevent stasis, and on the few occasions when he has been constipated there has been no return of the bacilluria.

Case 2.—A. M., man, aged 47, came to me in March, 1915, complaining of uneasiness over the bladder. He had been treated for "uric acid" at Vichy, in France, and for stricture in Paris twelve years before. He had a residual of 10 c.c. with some blood in the urine. His trouble was attributed to stricture, as cystoscopic examination failed to reveal any lesions in the bladder. It was noticed that he had colon bacilli in the urine, but their presence was naturally attributed to the stricture. The urethra was dilated until we could pass a No. 28 Charrière sound without difficulty. The uneasiness over the bladder still remained and he still had bacteriuria.

A second cystoscopic examination, made with the Garringer instrument, showed that he had a posterior transverse bar just inside the bladder neck, and a small glandular prostatic tumor on the right side just outside the bladder neck; the bar was removed through a suprapubic incision by Young's punch, and the tumor by enucleation, July 9, 1915. Recovery was perfect. In September, however, he was still complaining of the uneasy feeling over the pubes, and he still had colon bacilli in the urine, together with great frequency. In December the urine continued cloudy, and the patient was again showing signs of slight but steadily increasing

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

residual urine. In the meantime I had noticed distortion of the image of the neck on the left side of the bladder with the appearance of a tumor of the prostate on this side.

Under daily treatments with local antiseptics, phenol (carbolic acid), 1 per cent. in boric acid solution, and silver nitrate solutions and the use of the Kollman dilator, in February, 1917, there was no residual urine, but the urine still contained pus and swarmed with colon bacilli, and this condition continued steadily. In January, 1917, I began to place importance on the fact that the man was chronically constipated. Ureteral catheterizations showed that he had colon bacillus bacteriuria in the pelves of both kidneys. I had the intestine examined with the roentgen ray and found that there was a stasis in the ascending colon with an old adhered appendix apparently attached to the top of the bladder. April 5, 1917, Dr. Rea Smith and I performed a laparotomy. We found the ascending colon twisted on itself. The deformity appeared to be prenatal more than inflammatory, but it was adherent to the transverse colon and to the omentum, almost its entire length. We broke up the adhesions, straightened out the intestine, and patched the raw places with mobilized omentum.

Recovery was very slow but complete, and on May 5 the patient was having natural bowel movements, a thing he had not had since boyhood. The urine was still full of colon bacilli. May 8, I performed a perineal prostatectomy and removed the growth on the left side, which I had suspected to be cancerous because of its rapid development after the suprapubic operation, and straightened out an adhered verumontanum. Thus I took away the nest from which the infection started and removed the obstruction to the exit of urine, which kept up the infection, and brought the man into a condition in which a cure could take place.

The result is that today he has no longer any uneasy feeling over the bladder, he lies in comfort all night, the urine is perfectly clear and free of colon bacilli, he passes it naturally, he has bowel passages without the use of laxatives, and he is to all appearances a perfectly normal and well person.

EPIDEMIC PNEUMONIA (SPANISH INFLUENZA) IN PREGNANCY

EFFECT IN ONE HUNDRED AND ONE CASES

WESLEY J. WOOLSTON, M.D.
Attending Gynecologist, Cook County and Wesley Hospitals; Assistant Professor of Gynecology and Surgery, University of Illinois College of Medicine

AND

D. O. CONLEY, A.B., M.D.
Resident Physician, Cook County Hospital

CHICAGO

During the recent epidemic of pneumonia, or so-called Spanish influenza, 2,154 patients were admitted to Cook County Hospital between Sept. 18 and Nov. 5, 1918. Of this number, 101 were pregnant women.

Of these 101 cases of pneumonia, complicated by pregnancy, fifty-two died, giving a mortality of 51.4 per cent., as compared with a mortality of 719, or 33.3 per cent., of the 2,154 patients admitted to the general hospital. This shows a relatively higher death rate by 18.1 per cent. in the pregnant women. These apparently high percentages of mortality may be explained in part by the condition of the average patient on entrance to this hospital.

The Cook County Hospital received by far the largest majority of the patients during this epidemic, all of whom were from the poorer classes of the population. The patients were all extremely ill on entrance, many dying in ambulances on the way to the hospital, many in the examining room, and others while on the way to the wards. Of the fifty-two deaths occurring in the pregnant women observed, 53 per cent. died within the first twenty-four hours and 73 per cent. in the first forty-eight hours after admission.

Of the fifty-two deaths, in thirty-nine, or 75 per cent., an interruption of pregnancy occurred, and in a great majority of these cases this occurred within twenty-four hours preceding death. These figures include abortions, premature labor and labor at or about term. Interruption of pregnancy occurred with equal frequency, irrespective of the month of gestation.

Thirteen, or 25 per cent. of the patients remained pregnant at death, and practically all of these were in the fifth to seventh month of pregnancy. Seven of these were in the seventh month, three in the sixth month, two in the fifth month, and one in the third month of pregnancy.

Of the forty-nine patients discharged, twenty-one, or 42.7 per cent., aborted or went into labor prematurely. The remainder of these were pregnant at the time of discharge.

The cause of this frequency of interruption of pregnancy is uncertain. The fact that by far the greatest majority of abortions or premature labors occurred within twenty-four hours after death, at which time the patients were extremely toxic, would lead one to assume that probably this condition, associated perhaps with the lack of proper oxygenation of the fetal blood, was responsible for this frequency. The cough, which was a constant feature in these cases, undoubtedly played a part in the interruption of the pregnancy. The exertion incident to abortion or labor also tended to exert a harmful influence on the mother.

The most prominent feature noted during the clinical course of the disease was the apparent ease of abortion or premature labor, its rapidity and the apparent lack of pain incident to it. The mental state of the patient due to the toxemia may possibly have accounted for the freedom from pain. In term labors, the duration seemed to be no longer than that of normal labor.

The bleeding incident to labor, which would be equivalent to venesection (a therapeutic measure suggested when cyanosis appears) did not appear to affect the clinical course of the disease.

Complications were few in this series of cases. One case of empyema of the streptococcic type developed, the contents of the pleural cavity being a reddish-brown fluid. The empyema developed late, as has been characteristic of the cases following this type of pneumonia. Four patients developed suppurative otitis media.

Blood counts revealed the characteristic leukopenia, the degree of leukopenia varying with the severity of infection. The white cell count gradually increased as improvement occurred. Five patients, at the onset, gave a true leukocytosis of from 15,000 to 20,000. All of these patients recovered.

Of the twenty-two babies born, two developed definite symptoms of bronchial pneumonia within from eighteen to twenty-four hours after birth. This short interval after birth would make it difficult to say that infection did not occur in utero. Lung punctures of the stillborn gave negative cultures, however.

CONCLUSIONS

The death rate among pregnant women is materially higher than among nonpregnant women.

The frequency of the interruption of pregnancy in epidemic pneumonia is very high.

Abortion occurs with relative ease and lack of pain.

In the majority of cases, death follows within twenty-four hours after emptying of the uterus.

The percentage of recoveries after interruption of pregnancy is small.

THE PROPHYLACTIC VALUE OF LEARY'S VACCINE

HARRY LEE BARNES, M.D.
WALLUM LAKE, R. I.

As an institution offers unusual advantages for the study of an epidemic and the measures for its control, a record of our experience with influenza vaccine at the state sanatorium may not be without value. The institution had about 225 patients and ninety-four employees. During the last two weeks of September, 1918, four employees and five patients contracted influenza. These patients were all in one ward of the hospital and were apparently infected from a patient who visited Woonsocket. They were isolated in rooms and a cubicle of the ward, and the disease did not spread.

INCIDENCE OF INFLUENZA AMONG VACCINATED AND UNVACCINATED

Hospital 2	14	1	7	24	0	0
Children	32	0	0	1	0	0
Employees	27	7	26	28	7	25
Total	152	25	16	113	23	20

The four employees were isolated in their rooms. September 29, all patients and employees, with few exceptions, were forbidden to receive visitors or leave the institution. We were free from influenza, which was at the height of the epidemic in the surrounding country, until October 10, when a woman patient admitted on October 9 developed the disease. October 14, a patient who slept near this patient developed influenza. October 22, the first case developed in the men's ward of the sanatorium, and from there the disease spread to the employees, until there had been a total of eighty-two cases, or 25 per cent. of the total population. All of the 114 young adults, including some expatient employees sleeping in the east and west wards, were probably well exposed to the disease and furnish the best opportunity to estimate its morbidity. Counting all cases that occurred before and after vaccination, 45, or 40 per cent., developed influenza. October 22 and the few days succeeding, influenza vaccine furnished through the courtesy of Dr. Timothy Leary of the Tufts Medical School was given to 172 employees and patients. The doses were 400, 800 and 1,200 million at twenty-four hour intervals.

In computing the incidence of the disease for comparison between vaccinated and unvaccinated, no cases were counted that developed before the vaccine was given, and no patient has been counted as vaccinated unless he received the three doses. Before the arrival of the vaccine, eight cases that terminated fatally had developed.

In estimating the value of the vaccine, it would seem clear that the children should be deducted from the total because they were quarantined and so far as known were not exposed to the disease. If the children are deducted, the influenza incidence was 20 per cent. among both vaccinated and unvaccinated. It would also appear preferable to deduct the two hospital wards which had only one case each which were so promptly isolated that the exposure probably was insufficient to test the vaccine. If these wards are deducted, ninety vaccinated persons furnished twenty-four cases, or an incidence of 26 per cent., while sixty-four unvaccinated persons furnished twenty-two cases, or an incidence of 34 per cent. In twenty-five influenza cases following vaccination, four patients, or 16 per cent., died. In fifty-seven influenza cases among the unvaccinated, the mortality was nine, or 15.8 per cent.

CONCLUSION

The morbidity was only slightly lower among the vaccinated, and the mortality among those who developed influenza was practically the same whether vaccinated or unvaccinated.

Military Medicine and Surgery

THE PANDEMIC IN THE ARMY CAMPS*

GEORGE A SOPER, PH.D., M.D.
Major, S. C., U. S. Army
WASHINGTON, D. C.

The pandemic in the Army camps was a part of the great outburst that swept over the United States in September and October, 1918. This, in turn, was a manifestation of the still larger visitation that was to cover most, if not all, of the world.

As soon as the pandemic appeared, each camp and other station of troops was required to keep the Surgeon-General informed of the appearance and progress of the disease. Daily and weekly telegraphic reports were sent in giving the number of new cases of influenza and pneumonia and other details. Most of the statistical data presented here are taken from these reports.

Were it not for the pulmonary complication which has accompanied it, few would doubt that the disease was influenza. Its epidemic character, its clinical aspects and its bacteriology, so far as they have been studied, all point to that disease. It will consequently be called influenza here.

As to the lung complication, that is a similar matter. Objection has been made to the use of the term "pneumonia" to describe it. As yet no other official designation has been given it. It may or may not be a part of the original disease. Pending further investigation, and since it must be given some name in this report, it will be called pneumonia here.

Had it not been for the pneumonia, the pandemic would not have attracted much attention. Epidemics of so-called "colds" and other respiratory diseases occur every fall, and if the typical influenza of today does not bear a close resemblance to these familiar infections, there have been many cases in which the difference was not discernible. It took the pneumonia with its high mortality to command attention. The pneumonia places this outbreak among the most striking pandemics of modern times.

---

* From the Division of Infectious Diseases and Laboratories, Medical Department, U. S. Army.

Excluding the pneumonia, the influenza of September and October seems to be identical with the influenza that visited the Army training camps in the United States last March and April. That it attracted little notice then was due to its mild character.[1] The influenza which until recently has been reported from Europe appears to occupy a position between these two so far as severity is concerned.

Apparently there have been three visitations, or waves, each succeeding one being more severe, more widespread and more fatal than its predecessors. This fact may or may not have significance for the future. It is possible that there will be another wave. There may be one or more. It is equally possible that there will be none. There is no firm ground on which to base a prediction one way or the other. Considering the gravity of the matter, it would be unwise to assume that we are entirely done with the disease.

During the period from Sept. 12 to Nov. 1, 1918, inclusive, there were 306,719 cases of influenza reported among the troops in America. During the same time there were 48,079 cases of pneumonia and 19,429 deaths. The total strength of troops may be taken as one and a half million. Therefore it is approximately correct to say that about one in every five had influenza, that of these about one in six developed pneumonia, and that of the pneumonia patients about two out of five died.

The country as a whole suffered severely but not so greatly in proportion to the population as did the camps. Up to and including October 26, a total of 86,045 deaths from influenza and pneumonia had been reported to the United States Public Health Service. This figure is incomplete, since it includes no report from some states and only partial reports from others; in many states deaths for cities only were included.

In the forty-five principal cities for which statistics are available, 3.24 per thousand are reported to have died. There were 127,654 deaths from all causes. Had there been no epidemic of influenza-pneumonia, it is estimated that there would have been 47,967 deaths. The difference therefore represents the deaths due to the pandemic: 79,687. If this rate prevailed throughout the continental United States, there would have been 341,021 deaths. To this must be added the 19,429 in the camps, making a total of 360,450 deaths. These figures are not estimates—they are not even good guesses; but they serve to show the scale on which the pandemic operated.

I. The Statistical Facts

THE OUTBREAK

The first report that a serious epidemic existed in any camp came from Devens, at Ayer, Mass. September 16, the camp sanitary inspector, reporting through the camp surgeon to the Surgeon-General of the Army, announced that an epidemic of so-called "Spanish influenza" had broken out at Devens as a part of a general epidemic that had attacked Boston and the neighboring states and towns some weeks before.

The Devens epidemic is supposed to have commenced, Sept. 7, 1918, in D Company, Forty-Second Infantry. On that date a case of supposed meningitis was sent to the hospital from this company; on the following day twelve cases were sent for observation. These proved to be influenza. By the 16th, thirty-seven cases had gone from the same company. One death from pneumonia had occurred. Almost simultaneously, other cases appeared in other organizations. By September 12 the total number of patients that had been admitted was 599. The disease spread rapidly, in spite of the measures taken to check it. September 20, the epidemic reached its maximum intensity. On that day, 1,543 new cases were reported as having been admitted to sick report. After reaching this high point the number of new cases rapidly became less, so that by the end of the month there were less than 100 new cases reported per day.

Meanwhile, pneumonia had become a frequent and fatal accompaniment of the influenza. Fifty new cases were reported, September 19, less than two weeks after the influenza had been discovered. The number rapidly increased: September 24, there were 342 new cases. The number each day remained at about 200 for four days; then there was a decrease, until, before the end of the month, forty per day had been reached. By October 6, the incidence had fallen to ten or so a day. Through the rest of the month the number varied between three and seventeen per day. There was no return to large numbers.

TABLE 1.—THE RISE AND FALL OF THE EPIDEMIC AT CAMP DEVENS

	Duration, Days	Cases Influenza	Cases Pneumonia	Deaths
Rise (Sept. 12-19)............	8	3,283	43	16
Peak (Sept. 20-21)...........	2	2,722	205	43
Rapid decline (Sept. 22-29)...	8	3,141	1,495	298
Slow decline (Sept. 30-Oct. 18)	19	571	571	310

The Devens outbreak, so far as may be understood from the records at hand, could be divided into four parts, as shown in Table 1. It will be observed that the rise of the epidemic covered a period of about eight days; the peak, two days; the rapid decline, eight days, and the slow decline, nineteen days. Half of the deaths and nearly three quarters of the pneumonia occurred within less than three weeks of the outbreak.

CHARACTERISTICS OF THE TYPICAL EPIDEMIC

The characteristics of the Devens epidemic have been described here because they represent what has occurred at many camps. The earliest cases have often escaped identification. They have sometimes been taken for cases of food poisoning, meningitis or one of the common exanthems. The disease, which is epidemic, bears little resemblance to the coryzas and other respiratory affections to which the term "influenza" has been generally applied for the last twenty years. The so-called influenzas of ordinary times seem to have no relation to the present disease. Yet with a knowledge that influenza was in the vicinity, it is probable that cases of other respiratory infections have often been reported as that disease

---

[1] A report by the present writer, on an influenza epidemic in the Oglethorpe camps in March, 1918, may be found in abstract in the Journal of Laboratory and Clinical Medicine, 1918, 3, 46-49, and the Military Surgeon, 1918, 43, 398-402.

The leading symptoms in the typical cases are severe headache, chills or chilliness, pains in the back and legs, temperature sometimes as high as 104, great prostration, and drowsiness. Occasionally there are nervous symptoms; sometimes, but not always, the eyes and the air passages of the nose and throat are affected; there may be gastro-intestinal disturbances. The onset is sudden.

The fact that an epidemic existed in a camp has been generally recognized when the number of new cases has amounted to 100 or more per day. The incidence then increases rapidly. Sometimes the records show a great number of cases at the start, and there are marked fluctuations in the daily incidence as the epidemic continues. Striking irregularities do not represent the way in which the disease occurs, but are to be accounted for by the stress and difficulty with which the returns are collected. The greatest number of new cases reported for any day has often considerably exceeded 1,500 in a camp. At Devens the maximum was 1,543, at Grant, 1,810 and at Custer, 1,764.

The principal camp outbreaks have been charted as a part of the routine work of watching the progress of the pandemic. In making these charts it has been found convenient to mark time along the horizontal scale, giving one fifth of an inch to a day. The daily incidence of cases has been measured vertically, one inch representing 100 cases. So charted there is much similarity among the curves and especially among the members of certain groups of them. The explosive character of the infection is plainly indicated in most, as are the short duration, large incidence and rapid subsidence. The curves are never smooth, but are jagged, with steep inclines between the peaks and valleys. Only in exceptional camps has there been a recurring wave of noteworthy proportions during the course of the epidemic.

In another series of charts, the daily incidence has been plotted as rates, thus making allowance for the changes in strength that have occurred. In a third series the jagged irregularities have been eliminated, and smooth curves trace the rise and fall of the influenza and pneumonia. This has been done for all the camps. These pictures show as clearly as the data permit how the disease has come and gone. The charts furnish an invaluable means of analyzing and comparing the several camp epidemics. They have made plain many instructive facts and have pointed the way to many useful conclusions. But to go into the question of the individual epidemics would carry this discussion beyond its proper bounds.

Stated briefly, the influenza has usually occurred as an explosion, probably showing irregularities in the reporting. The maximum effect has been felt within about ten days after the onset. The duration has been less than three weeks, in most instances.

Within about a week after the outbreak of the influenza, there occurs an ominous prevalence of pneumonia. The pneumonia does not exist as a separate epidemic, but is always a follower of influenza. How the two diseases are related is not positively known. It is clear that the influenza paves the way for the pneumonia, if it does not actually produce it. Most of the pneumonia is of the lobular type and presents various unusual aspects. The time of greatest incidence is usually about a week after the greatest incidence of influenza.

The curves of incidence of pneumonia, when plotted as has already been explained, and with the same scales, are wholly different from those of influenza. The pneumonia does not appear to have been explosive. The curves for the different camps do not resemble one another. One would say that the pneumonia bore no fixed relation whatever to the influenza, except that it followed it.

SPREAD OF THE PANDEMIC

The second camp to report an epidemic, following Devens, was Upton, on Long Island, N. Y.; the third was Lee, in Virginia. Dix, in New Jersey, and Jackson, in South Carolina, followed immediately. Hoboken, N. J., Syracuse, N. Y., Gordon, in Georgia, and Humphreys, in Virginia, all reported on the same day. Within a week from the start, nine large camps in widely separated parts of the country were attacked. Others followed in rapid succession. Table 2 gives the order, according to the daily telegraphic reports.

TABLE 2.—ORDER IN WHICH THE CAMPS WERE ATTACKED

Order		Date	Order		Date
1	Devens	Sept. 12	11	Greene	[illegible]
2	Upton	Sept. 13	11	[illegible]	[illegible]
3	Lee	Sept. 17	12	[illegible]	[illegible]
4	Dix	Sept. 18	12	Bowie	Sept. 27
4	Jackson	Sept. 18	13	Johnston	Sept. 28
5	Hoboken	Sept. 19	13	Sheridan	[illegible]
5	Syracuse	Sept. 19	13	[illegible]	[illegible]
5	Gordon	Sept. 19	14	[illegible]	[illegible]
5	Humphreys	Sept. 19	14	[illegible]	[illegible]
6	Logan	Sept. 20	15	Custer	Sept. 30
6	Funston	Sept. 20	15	Hancock	Sept. 30
6	Meade	Sept. 20	16	Travis	Oct. 1
7	Grant	Sept. 22	17	Cody	Oct. 3
7	Taylor	Sept. 22	18	Forrest	Oct. 6
8	Sevier	Sept. 23	19	MacArthur	Oct. 7
8	Lewis	Sept. 23	20	Fremont	Oct. 8
8	Newport News	Sept. 23	21	Wadsworth	Oct. 11
9	Pike	Sept. 24	21	Wheeler	Oct. 11
10	Beauregard	Sept. 25	21	Greenleaf	Oct. 11
10	Eustis	Sept. 25	22	Las Casas	Oct. 29

During this period, September 12 to 30, inclusive, thirty-one camps were attacked. The epidemics in this group had subsided in every case by November 1, with the exception of Hoboken, Kearney, Bowie and Shelby. Ten additional camps were attacked during October, completing the list of all the important camps in the United States. Las Casas, Porto Rico, which is last on the list, did not report cases until October 29, on which date an accumulation of 562 admissions was reported.

COMPARISON BETWEEN TENT AND BARRACK CAMPS

Of the thirty camps attacked during September, eighteen were barrack camps, eleven were tent camps, and two were ports of embarkation. During October, eight tent camps and two cantonments were attacked.

The appearance of the pandemic in the tent camps was apparently delayed by reason of their position. They were mostly in Southern states and not immediately adjacent to the seaboard. Speaking generally, the pandemic spread from the sea inland, and from the Northeast to the West and South. There is no reason to suppose that it traveled more rapidly than persons could travel. In cases in which it has appeared to do so, it is probable that infection has been established from foci before the latter were recognized, or from earlier outbreaks.

The pandemic appeared seven days later in the camps than in the cantonments, when these two kinds of camps are compared as groups. Taking the barrack camps as one group and the tent camps as another, it appears that the disease spread rapidly in both—as rapidly in the one as in the other. There was, in fact, a remarkable similarity in the rate of spread in each kind of camp.

Interest attaches to a comparison between the relative severity with which the tent and barrack camps were attacked for a number of reasons. Among these is the fact that the tents afforded a greater separation of the men than did the barracks. The distribution of cases in cantonments and tent camps during the period of September 12 to October 31, inclusive, is given in Table 3.

TABLE 3.—DISTRIBUTION OF CASES IN CANTONMENTS AND TENT CAMPS, SEPTEMBER 12-OCTOBER 31

	Cantonments	Tent Camps
Camps attacked	20	19
Combined strength	748,632	313,362
Influenza	158,104	69,761
Pneumonia	30,099	9,740
Deaths	10,533	2,923
Per cent. having influenza	21.1	22.2
Per cent. having influenza and pneumonia	19.0	13.9
Case fatality of pneumonia	35.0	30.1

It should be noted that while the number of cases of influenza reported by the cantonments has been more than twice the number reported by the tent camps, the strength of the cantonments has been greater in almost the same proportion. When rates instead of cases are considered there appears to have been less difference in the severity of the pandemic than might be expected. But if there has been as much influenza in the one kind of camp as in the other, there has been no similarity in respect to the incidence or fatality of pneumonia.

The percentage of cases of influenza that developed *pneumonia* has been greater in the cantonments than in the tent camps; 9 per cent. in the one, against 13.9 in the other. The case fatality of pneumonia has also been greater in the cantonments than in the tent camps.

In order to study more carefully the progress of the pandemic in the cantonments and tent camps, Table 4 was prepared. Here the camps and cantonments are divided into two groups; the figures given are in the form of rates (annual per thousand). These show the suddenness with which the epidemic appeared, how rapidly it rose to its point of greatest intensity, and how it subsided.

TABLE 4.—PROGRESS OF THE INFLUENZA IN THE TENT AND BARRACK CAMPS

Cantonments	Annual Rates	Date	Annual Rates	Tent Camps
First report	255	Sept. 12		
	995	Sept. 19	73	First report
Peak	5,765	Oct. 4	1,850	
	2,220	Oct. 10	3,865	Peak
	180	Oct. 26	605	Lowest since peak
Lowest since peak	140	Oct. 28	1,610	
Daily incidence	330	Oct. 31	915	Daily incidence

According to this table, the tent camps followed the barrack camps in point of time but not in violence of outbreak.

COMPARISON BETWEEN CAMPS ACCORDING TO THE PROPORTION OF MEN ATTACKED

So much for the comparison between the tent and barrack camps. Turning attention now to the camps with regard solely to the proportion of men attacked, the camps may be thus divided into groups according to the proportion of men attacked with influenza: Group 1, from 30 to 50 per cent.; Group 2, from 20 to 30 per cent.; Group 3, from 10 to 20 per cent.; Group 4, less than 10 per cent.

Cody leads the first group with 49.8 per cent. of all troops attacked. Other camps in this group are Beauregard, 39.6 per cent.; Wadsworth, 38.6; Bowie, 38.1; Hoboken, 30.5, and Devens, 30.1.

Dodge has had 20 per cent. of all troops attacked and is the first in Group 2. Fourteen other camps fall in this group: Custer, MacArthur, Meade, Pike, Grant, Greene, Funston, Forrest, Travis, Logan, Lee, Hancock, Sheridan and Greenleaf.

Fifteen camps are contained in the third group. Fremont, Lewis and Wheeler, standing at the foot of the list, made up Group 4.

As to fatalities from pneumonia, Grant and Sherman are foremost. At Sherman, 61.3 per cent. of all pneumonia patients have died, and at Grant 45.7 per cent. While the case fatality has been still higher at Wadsworth, Forrest and Greenleaf, the total deaths reported by these camps have been but little more than one third of the total reported by Sherman alone. Special mention should be made of the situation at Wheeler. Only seventy cases of influenza have been reported, but a total of 361 cases of pneumonia and sixty-one deaths have occurred.

SEVERITY IN RELATION TO THE ORDER OF ATTACK

Some interesting facts are revealed when the camps are arranged according to the dates of attack, as shown in Table 5. In this table the camps have been arranged in groups of five wherein are indicated camps reporting epidemics at about the same general stage of the pandemic. This table merits careful study.

TABLE 5.—CASES AND DEATHS AMONG TWENTY CAMPS ARRANGED ACCORDING TO THE CHRONOLOGICAL ORDER OF THEIR ATTACK

	Total Cases Infl.	Total Cases Pneu.	Total Deaths Pneu.	Per Cent. Attacked Infl.	Per Cent. Pneu. to Infl.	Per Cent. Deaths Pneu.
Five camps* attacked (Sept. 12-18)	46,569	7,968	3,000	21.4	17.1	37.6
Five camps† attacked (Sept. 22-24)	44,000	8,011	2,867	21.4	18.2	35.7
Five camps‡ attacked (Sept. 29-Oct. 1)	36,044	7,387	2,484	23.8	21.8	31.7
Five camps§ attacked (Oct. 3-11)	20,096	1,837	579	28.9	8.9	31.5

* Devens, Upton, Lee, Dix, Jackson.
† Grant, Taylor, Sevier, Pike, Newport News.
‡ Sherman, Dodge, Shelby, Custer, Travis.
§ Cody, Forrest, MacArthur, Wadsworth, Greenleaf.

It shows that the percentage attacked by influenza increased as the pandemic continued. This is most strikingly indicated in the group which was attacked from October 3 to 11. This group reported 28.9 per cent. of all troops stricken, as compared with 21.4 per cent. in the first group. The inference is that the disease increased in infectivity, or that as the pandemic spread it reached troops who were more susceptible. The latter is probably the fact.

The percentage of influenza cases that developed pneumonia increased as the pandemic proceeded, until the last group (attacked from October 3 to 11) was reached, when a notable drop from 21.8 to 8.9 per cent.

is indicated. This decrease is remarkable. It is probably due to the fact that all the cases of pneumonia that would occur had not yet developed in these camps. Cody, Forrest, Wadsworth and Greenleaf, all in the fourth group, were just passing the peak of influenza during the last four days of October.

It is noteworthy that the case fatality in pneumonia decreased with each successive group.

SEVERITY IN RELATION TO GEOGRAPHIC LOCATION

On considering the camps when grouped according to their location, it has been found that those in the Southwestern section, including the states of Texas, Arkansas, Louisiana and New Mexico, had relatively more men attacked by influenza than did any others. No camp in this group had less than 20 per cent. attacked, and three (Cody, Beauregard and Bowie) exceeded 30 per cent. For the period of the epidemic including October 31, Cody was first on the list of all camps, with 49.8 per cent. of all troops attacked. No explanation is offered for this remarkable fact.

An arrangement of the camps both according to their percentages of men attacked and geographic location is given in Table 6.

TABLE 6.—RELATIVE INCIDENCE OF INFLUENZA IN THE CAMPS ARRANGED GEOGRAPHICALLY

Per Cent. Attacked	South-western	Atlantic Coast	South-eastern	North Central	Pacific Coast
30 to 50	Beauregard Cody Bowie	Hoboken Devens	Wadsworth		
20 to 30	Dodge MacArthur Pike Travis Logan	Meade Lee	Greenleaf Hancock Sheridan	Custer Grant Funston	
10 to 20		Newport News Dix Upton Syracuse Eustis	McClellan Johnston Jackson Shelby Sevier Gordon	Taylor Sherman	Kearney

In the Atlantic Coast group, two camps had more than 30 per cent. attacked; two camps had from 20 to 30 per cent., and five had from 10 to 20. This group is second on the list when the prevalence of influenza is considered.

TABLE 7.—RELATIVE INCIDENCE OF PNEUMONIA FOLLOWING INFLUENZA IN THE CAMPS ARRANGED GEOGRAPHICALLY

Per Cent. Attacked	South-western	Atlantic Coast	South-eastern	North Central	Pacific Coast
30 to 40				Sherman	Lewis
20 to 30	Travis	Meade	McClellan	Taylor Grant Custer	
10 to 20	Beauregard MacArthur Pike Logan	Upton Syracuse Hoboken Devens Lee Dix Newport News	Sevier Greene Hancock Sheridan Jackson Gordon Johnston	Dodge Funston	Fremont
Less than 10	Bowie	Eustis	Wadsworth Greenleaf Shelby		Kearney

One camp in the Southeastern group exceeded 30, and three had from 20 to 30 per cent. of all troops attacked. Of the seven remaining camps of the group, six had from 10 to 20 per cent., and one had less than 10 per cent. The North Central group had no camp that exceeded 30 per cent. Of the five camps considered in this group, three had from 20 to 30 per cent. of men attacked, and two had from 10 to 20. The influenza appears to have been least prevalent in the Pacific Coast group. One camp had from 10 to 20 per cent. attacked, and two had less than 10 per cent.

Pneumonia following influenza was most prevalent in the North Central group of camps. Sherman, in this group, had 35.7 per cent. of all influenza cases develop pneumonia. Three camps had from 20 to 30 per cent.

Lewis, the only other camp to exceed 30 per cent., is in the Pacific Coast group. Two other camps in this group reported less than 20 per cent. Lewis is farthest north. The Atlantic Coast group had one camp with from 20 to 30 per cent. of pneumonias; seven with from 10 to 20 per cent., and one with less than 10. Rates distributed in the Southeastern group were: from 20 to 30 per cent. at McClellan; from 10 to 20 per cent. in seven camps; less than 10 per cent. in three camps.

TABLE 8.—RELATIVE CASE FATALITY OF PNEUMONIA IN THE REGIONAL GROUPS OF CAMPS

Group	More than 60 Per Cent.	40 to 60 Per Cent.	30 to 40 Per Cent.	Less than 30 Per Cent.
Southeastern	1*	2	4	5
North Central	1	1	2	2
[illegible]	1	1	1	3
	...	2	5	2
	...	...	1	2

* Figures indicate number of camps.

The case fatality of pneumonia has been greater in the Southeastern, North Central and Southwestern groups than in the Atlantic and Pacific Coast groups.

TABLE 9.—AVERAGE PERIOD OF INCREASE, CREST AND RAPID DECLINE OF THE EPIDEMICS IN THE REGIONAL GROUPS OF CAMPS*

Group	Increase (Days)	Crest (Days)	Decline (Days)
Atlantic Coast	7	7	5
[illegible]	6	9	6
	6	4	6
	5	6	6

* Twenty-five camps are considered in this tabulation.

The increase has been most rapid in the Southwestern group: five days. The Southeastern and North Central groups reached the high point in six days. The Atlantic Coast group was on the increase for seven days. The average period of very high incidence was nine days in the Southeastern group. The shortest period of high incidence was four days, in the North Central group. The period of rapid decline was five days in the Atlantic Coast group, and six days in all other groups.

CASES OF INFLUENZA AND PNEUMONIA AND DEATHS IN THIRTY-EIGHT OF THE LARGEST CAMPS

Table 10 gives for each large camp the number of cases of influenza and pneumonia, percentages of troops attacked, percentages of deaths and the length of the epidemic in days. The camps have been arranged in the order of the percentage of men attacked in each.

Next, in Table 11, is given the total number of cases of influenza and pneumonia and deaths week by week from the beginning of the pandemic to November 1, for all troops in the United States. This table shows the remarkable activity of the influenza pandemic, considering the camps as a whole. Within these weeks it had reached its acme and had begun to decline. Its subsidence was as rapid as its rise. In the space of less than two months it had come and gone, leaving only a few cases in some of the camps in its trail.

TABLE 10.—INFLUENZA, PNEUMONIA AND DEATHS IN THE LARGE CAMPS, PERIOD SEPT. 12 TO OCT. 31, 1918, INCLUSIVE

	Cases Infl.	Cases Pneu.	Total Deaths	Per Cent. Attacked Infl.	Per Cent. Pneu. to Infl.	Per Cent. Deaths Pneu.	Duration Epidemic in Days
Group 1							
Cody	2,337	252	46	49.8	10.8	18.2	28
Beauregard	5,252	1,007	422	39.6	19.2	41.9	36
Wadsworth	5,505	357	60	38.6	6.5	16.9	20
Bowie	4,052	119	104	38.1	2.9	89.8	32
Hoboken	13,563	2,280	794	30.5	16.9	34.9	42
Devens	13,398	2,288	794	30.1	17.1	34.9	49
Group 2							
Dodge	9,398	1,847	570	29.0	19.7	30.8	32
Custer	11,626	2,437	669	29.0	20.9	27.8	31
MacArthur	6,010	852	188	28.1	14.1	20.4	24

II. The Handling of the Epidemic

ACTION BY THE SURGEON-GENERAL'S OFFICE

The steps that were taken to combat the pandemic may be divided into those followed by the direction and guidance of the Surgeon-General's Office at Washington, and those that the camps themselves initiated. These steps may be collectively described as having fallen under three heads, (1) isolation, (2) sanitation and (3) education.

1. By isolation is meant any and all procedures by which infected could be separated from the susceptible persons. Included in this list were steps for the prevention of crowding, quarantine, head to foot sleeping, the separation of heads at mess, and the use of cubicles and masks.

2. Under sanitation may be included the cleaning and airing of barracks and bedding, the oiling of floors to keep down the dust, the boiling of mess-kits and many other procedures.

3. Education, always a predominant motive in the Army, was applied as never before to the prevention of disease among troops. The medical officers were taught what to expect in the way of symptoms and what principles of prevention to put into effect. The men were taught something of the principles of disease transmission and how to carry out their part of the work of prevention. Orders were issued, lectures given, and examples shown. Throughout, the line gave cordial cooperation.

The following paragraphs give a summary of the action taken by the Surgeon-General's Office, and a brief account of what an inspector from that office saw when he visited one of the large camps.

Soon after the pandemic disclosed itself, a recommendation was made by the Acting Surgeon-General to the chief of staff that further increments of the draft be stopped and that all troop movements between infected and uninfected camps be checked. On recommendation, the Adjutant-General ordered the setting aside of buildings to supplement the base hospitals during the epidemic and the furnishing of all necessary unskilled labor for the hospital needs. On September 24, instructions were sent to all camp surgeons regarding the symptoms, epidemic aspects and methods of handling the disease. Large numbers of medical officers and nurses were hurried to the camps. Instructions were sent to buy locally any medical supplies not promptly obtainable through medical channels.

Special sanitary inspectors from the Surgeon-General's Office visited many of the camps with a view to investigating the situation and proposing any improvements that appeared possible in the methods of handling the situation. When thought necessary, camps were quarantined against the civil communities or vice versa, as appeared desirable to the Acting Surgeon-General in order to protect the troops or civilians or both. There was issued a set of a dozen rules on personal hygiene designed to aid the individual in maintaining health during the emergency.

REPORT OF AN INSPECTION OF A CAMP

Under date of September 30, there was sent to camp surgeons, surgeons of recruit depots and independent stations, department surgeons and officers in charge, Air Service Division, the report of a sanitary inspector from the Surgeon-General's Office to show the steps taken at one camp to handle the situation in a satisfactory manner and the recommendations for further improvement made by the inspector. The following abstract is taken from that report.

It should be stated that the policy of the Surgeon-General's Office has been to leave many of the details of camp management, so far as relates to sanitary and medical matters, to the camp authorities on the theory that they alone can be perfectly familiar with the local needs and resources, giving such aid in the way of recommendations as a general knowledge of the situation, and the correct principles to be observed, permit.

The inspection was made two weeks after the epidemic started. The epidemic was at its height: about one in ten of the command was sick with influenza. Of this number about a third were in hospital; the rest were in their quarters. There were 536 cases of pneumonia; there had been 253 deaths.

The report stated that there was no overcrowding. The barracks were marked with their maximum capacity on the basis of 45 square feet of floor space per man, and this was not exceeded. About one fourth of the entire number of troops was under canvas, five men to a tent. The men slept with head and feet alternating to increase the distance between heads as much as possible. In some of the barracks the "cubicle system" was contrived by means of shelter tents suspended between the beds in order to make the separation of the men more complete.

The heating arrangements were in operation in all the buildings, and the freest possible ventilation was enforced. Beds, bedding and clothing were kept outdoors all day, weather permitting. The tents were furled daily. All floors had been oiled once, and some twice, since the epidemic started. Overcoats and woolen underwear had been issued. There was ample bedding. The men who were not sick were kept outdoors all day. An officer was on duty in each barrack day and night.

The camp and barracks and messes were clean. Ample steps had been taken to eradicate flies. Dishes were boiled after each meal. When individual mess kits were used, they were washed in boiling water after each meal and actually boiled at intervals. There were no common drinking cups in use. Dust filled the air on the day of the inspector's visit and was very annoying.

Two thousand negroes who had arrived at camp from civil life between two and five days earlier had been put in an area by themselves and efficiently quarantined, the result being that no case of influenza had appeared among them.

THE HOSPITAL FACILITIES

The capacity of the base hospital had been increased by fitting up a group of eighteen company barracks, fortunately empty, and placing this annex under the base hospital administration. The annex was opened about ten days after the epidemic started, and had a capacity of 1,040 patients. It was described as in excellent condition. Each patient had 100 square feet of floor space; quartermaster cots were used with straw mattresses and the soldiers' own blankets. The Medical Department supplied sheets, pillows, pillow cases and pajamas. There were one female nurse and 186 enlisted men from the line on duty; 100 more nurses were expected. There were 977 patients; of these eighteen had pneumonia.

Ambulant cases, that is, influenza patients whose temperatures had been normal for from twenty-four to forty-eight hours, went out of their particular building to the nearest mess for meals. Men with abnormal temperatures were not allowed to go out to the lavatories. Influenza patients in hospital were being kept from seven to eight days; the rule was to keep them till the temperature had been normal four days.

The attendants wore masks, but cubicles had not been installed. The order and system were reported by the inspector as most commendable.

Further to supplement the base hospital, there was a second group of company barracks. These were run as field hospitals. Their capacity was 700 patients. The conditions here were not quite so good.

The base hospital was stated to be in excellent condition. There were 2,800 patients here, about 300 of whom were venereal and in tents; about 400 others were to be transferred to the annex three quarters of a mile away. There was only slight crowding. The porches were occupied by beds. All pneumonia patients in wards were cubicled, but not those on the porches, though the beds were close together. The influenza patients were not cubicled because of lack of sheets, but there was no serious shortage of supplies. At the outset the camp surgeon directed the camp supply officer to purchase whatever was necessary.

There was one ward full of sick nurses, of whom thirty were said to have pneumonia. One nurse, one dietitian, one medical officer and one dental officer had died. The patients were arranged heads and feet alternatively. The attendants were all masked. The ventilation was ample. The supply of medical officers, nurses, laboratory workers and enlisted men, Medical Department, was being increased. Numerous circulars relative to the prevention of influenza and its complications had been issued by the camp authorities, and these were very complete and satisfactory.

THE INSPECTOR'S RECOMMENDATIONS

In his reports to the Acting Surgeon-General and to the commanding general of the troops, the inspector described the whole situation as well handled. Nevertheless it was recommended among other things that no soldiers be returned to duty after influenza until at least ten days after their temperature had become normal; that all influenza patients should have at least 100 square feet of floor space and be screened from each other, the idea being to prevent pneumonia, and that no influenza patients be treated in barracks that were in part occupied by healthy soldiers.

It was recommended that both in barracks and tents the cubicle system be adopted for all healthy men by the use of the shelter tent supported at one corner of the bed by a stick or hung from the ceiling by wire, and that mess tables be so arranged that the men should sit either on one side of the table alone, or else that the occupants of the two sides of the table be separated by a screen of cheese cloth suspended above the middle of the table.

It was recommended that the quarantine of the camp against the surrounding country, and of the surrounding country against the camp, be continued and that no one be allowed to enter or leave the camp except the friends and relatives of the seriously ill; that as soon as the epidemic disappeared the population of the camp be reduced so as to be placed on the basis of 50 square feet per man; that improvised corridors covered with canvas be provided to connect the lavatories with the barracks which are used for hospital purposes; that steps be taken to prevent men from crowding together at post exchanges and about stoves in barracks; that the laying of dust in camps be expedited, and that great care be taken in disinfecting clinical thermometers.

Some of the recommendations made were already contemplated by the camp authorities or were under way, but not yet completed, the inspector stated, on account of lack of time or material.

III. The Cause of the Outbreak

CHARACTER OF THE INFECTION

It is usually impossible accurately to trace the origin and paths of spread of a pandemic like the present one. The popular demand that this be done is natural but unreasonable. It rests on the supposition that disease can be run down like a criminal; that visible and recognizable traces are left by it. This is not always true. The pursuit is often so illusive that deductions stronger than inferences are not warranted regarding it. With a disease like influenza, the proof seldom amounts to complete demonstration. The routes of infection are generally hidden beneath a mass of imperfect observation, wrong theory and illogical deduction. Under the circumstances the best that can be done is to follow out the larger aspects of the question.

The present pandemic offers no exception to this rule. In the minds of thousands of persons the disease is hopelessly confused with minor respiratory diseases that have for years been loosely called influenza infections. Many do not know "Spanish influenza" when they see it, the symptoms being by no means easily recognized by those who have never had occasion to deal with it. And to the best informed there are many things about influenza that are shrouded in mystery. Consequently all that will be attempted here is the recording of some apparently well established facts and the drawing of some apparently safe inferences, leaving to others and especially to later investigators the task of interpreting the pandemic more fully.

These remarks seem to be called for by a demand for an explanation of the way in which the pandemic spread from one organization to another in a camp, from one camp to another, and from the camps to the towns and vice versa.

THE MEANS OF TRANSMISSION

First, it is necessary clearly to understand that the influenza to which attention is now called is a specific infective disease like cholera, typhoid, smallpox and others, and it has, at all times and in all places, shown a uniformity in its configuration and in its cause such as almost no other infectious disease has. These words were written nearly two generations ago by Hirsch, but they seem to have been forgotten. They were forgotten in England in 1889, when the pandemic of influenza broke out in that country and for some time failed of recognition. They were forgotten in the United States, where for nearly thirty years no sensational outbreak of the disease had occurred.

The disease is carried from place to place by persons, not things or by the general atmosphere, as was once supposed. Its rapidity of spread is due to its great infectivity, short period of incubation, missed cases, and absence of timely precautionary measures. An epidemic does not easily start, but once the flame is well kindled a conflagration occurs which cannot be stopped. The epidemics stop themselves. This they do either by an exhaustion of the susceptible material, by a reduction in the virulence of the causative agent, or both.

The disease has been taken into camps, from camp to camp, from camps to towns, and from towns to towns, by people. It cannot be said to have been proved that this is the only way in which it has been transmitted, but there seems no reason to look for more probable ways—according to modern theories, all respiratory infections are conveyed by contact. The travel and mingling that occur under ordinary circumstances seem to be quite enough to account for the facts.

In theory and practice influenza is preventable, but it is very difficult to control under municipal and military conditions. It rarely happens that the necessary measures—chiefly based on the principle of isolation—are taken in time. In the present pandemic the disease, on more than one occasion, has been confined to certain wards of hospitals to the exclusion of others. It has visited some camps and some organizations more severely than others. It is not possible as yet to state to what extent it has been actually controlled in the camps.

The pandemic may truly be termed an epidemic of epidemics. Like all great outbreaks of this most infectious of communicable diseases, the epidemics have occurred with electric suddenness, and, acting like powerful, uncontrolled currents, have produced violent and eccentric effects. The disease never spreads slowly and insidiously. Wherever it occurs its presence is startling. A large proportion of the men in one company may be infected while those in the next company may entirely escape.

How far the pandemic will spread will apparently depend only on the epidemic vagaries of the disease and the amount of material on which it can feed. It is too early to foretell the end or to measure the damage that will be done before it diseappears. Apparently it is destined to have a world wide distribution.

It is not improbable that the pandemic may disappear from the United States as rapidly as it came, although most persons hold the opinion that its final disappearance will be gradual, the extinction of the disease being postponed for many months. It is already practically gone in most army camps. It may or may not return. In the pandemics that sweep over the earth at long intervals, recurring waves of greater or less degree, separated by some months, commonly occur.

THE INFECTIVE AGENT

The causative agent is generally believed to be the bacillus of Pfeiffer; the means of transfer, droplets of moisture from the mouth and objects recently contaminated by the buccal and nasal secretions of those who harbor the virus. It is a fundamental assumption that influenza is produced when, and only when, material from the mouth or nose of infected persons gets into the mouth or nose of some one who is susceptible. As is plainly recognized in respect to intestinal infections, the hand probably plays an important part in the transmission of influenza. Coughing and sneezing help greatly to spread the infection.

It has long been known that interchanges of bacteria occur commonly from mouth to mouth under ordinary conditions of social intercourse. Most of these organisms are harmless under normal conditions of health. That their capacity for harm is sometimes increased, sometimes reduced, according to various circumstances, is highly probable. What these circumstances are is conjectural.

The Pfeiffer bacillus is no stranger to America; it was known to be rather commonly present in healthy persons before the pandemic. To account for the virulence that seems to be possessed by this organism now it has been suggested that (1) something must have happened to increase its virulence, or (2) a new and more active strain of it appeared, or (3) the susceptibility of those attacked became reduced. Some persons hold that the causative agent has not been discovered and that the Pfeiffer bacillus is not really responsible for the disease. Some even go so far as to say that the disease is not influenza. With these disputed points ti is not necessary to deal here. All three of the numbered propositions in this paragraph are accepted as probable by the present writer.

The conditions that govern susceptibility to influenza are not understood. Good general health, absence of fatigue and of cold and hunger are methods of prevention which have long been advocated by many and which in spite of scientific criticism still have much to recommend them. Whatever conduces to low bodily tone is believed by most persons to favor infection. Some, however, hold that specific immunity either does or does not exist and that wet feet, insufficient bedding, chill, hunger and fatigue have nothing to do with susceptibility.

Vaccination against pneumonia is practicable; but such preventive treatment is in the experimental stage as respects influenza. As to natural immunity, one attack is believed to protect against another, and some people seem to be immune without ever having experienced an attack.

The weather has always been supposed to exert an influence on influenza—the very name is derived from the effect which extraterrestrial conditions were supposed to exert on it. But although there has been a great deal of study of this matter from early times to the present, little is known concerning it. It is possible that the weather this fall has aggravated the influenza and contributed to the incidence of the pneumonia. The pandemic appeared after a very hot season had suddenly been succeeded by a very cold one. After the pandemic was well started, a particularly long period of fine weather occurred. More important, perhaps, the weather also precipitated a large amount of other respiratory infections, such as always become prevalent at this season. There is little doubt that many of these cases have been mistaken for influenza.

The epidemics which occurred in the spring of 1918 were like those that took place in the fall, except that the disease was milder and there was less pneumonia in the spring. Until the late summer the influenza reported from Europe was of a relatively mild type. It seems to have been as infectious there as it is here. Reports coming from all parts of Europe indicate that the percentage of persons attacked was about the same as in America.

IMPORTATIONS OF A VIRULENT STRAIN

The origin of the influenza pandemic now sweeping the world is usually attributed to Spain. It is doubtful, however, whether the disease was first seen in Spain or the United States. Some have held that it was brought to the Western hemisphere from China.

Early in the spring of 1918, a disease of unknown origin is reported to have appeared in Spain with the symptoms of sudden onset, severe headache, pain in the back, fatigue and perhaps nausea. After three or four days the patient recovered. Influenza appeared in America early in March, being reported from Fort Oglethorpe, March 18, and from some other parts of the United States much earlier.

In the latter part of March the disease appeared in the American Expeditionary Force, in the French and British army, and in the civil population. About 25 per cent. of all who were exposed to the disease were attacked. The death rate was low. The first cases in Germany were among troops that fought with a (presumably infected) American regiment in July.

In September, the disease assumed a more serious character, being complicated with bronchopneumonia and septic pneumonia with a high mortality in some epidemics. The disease is said to have become more severe in Spain as the season advanced.

The first that was seen of the highly virulent infection in America was among shipping. During July and August a number of vessels plying between Europe and America experienced intense outbreaks of what was called "Spanish influenza." That patients with the disease were being brought into the country in this manner was stated in the daily press and in official reports in July.

Many patients were admitted to various ports of the United States from ships during June, July and August. The Navy has pointed out that the British steamship *Exeter,* which arrived from Liverpool, at Philadelphia, June 22, reported at quarantine that twenty-seven Lascars and an English quartermaster were ill with pneumonia. These patients, who were described as in a desperate condition, were removed to hospital. The opinion was reached that they had influenza.

July 7, the New York papers described an outbreak of "Spanish influenza" which had occurred on a troop ship returning to America. The vessel was compelled to put back into port, there not being enough of her crew left to handle her. This vessel was the Cunard Liner *Khiva,* which had left Liverpool, June 15. Six days later six of the crew were taken suddenly ill. Two days later the number was increased by fifteen. Next day there were fifteen more cases. The ship then, pursued by a submarine, put into Halifax. Ten days later it proceeded to New York. There were no deaths.

August 18 and subsequently, the New York papers described outbreaks of influenza on the *Rochambeau* and the *Nieuw Amsterdam.* On one of these vessels, twenty-one cases of influenza had occurred. Some of them developed pneumonia and were sent to St. Vincent's Hospital. According to the New York *Times* of July 18, 1918, influenza had been coming to New York on vessels since the early part of June.

According to a Navy bulletin, two steamships from Norway and one from another Scandinavian port arrived in New York, August 14 and 15, having a number of patients ill with influenza.

The Surgeon-General of the United States Public Health Service reported a sharp outbreak at Fort Morgan, near Mobile, Ala., during the month of August. At the same time a steamship arrived at Newport News with substantially the entire crew infected. The *Bergensford,* which arrived in New York, August 12, had during the voyage 200 cases of influenza.

The foregoing, which makes no claim to being a complete list, is sufficient to show that influenza was brought to the United States and to various ports on vessels from Europe through the whole summer. In some outbreaks there was a great deal of a fatal pneumonia.

The patients from the vessels were sent ashore and soon mingled with the civilian populations. There were thus scattered rather widely along the Atlantic seaboard sparks from which the pandemic not improbably arose. How abrupt were the appearance and spread is not yet perfectly clear. In arriving at an understanding of this point it is necessary to distinguish between the sudden appearance of the disease and its sudden recognition.

There is another and less definite explanation of the pandemic offered. It is less an explanation than a guess. The same kind of guess probably has been made ever since epidemics first visited the earth. It is that the marked virulence noted in the recent pandemic is due to the weather. The supposition is that in some way not determined, the mild influenza of last spring became greatly intensified this fall.

That the disease appeared suddenly in the camps and ran a meteoric career is clear enough. Evidence presented in Table 12 indicates that its appearance and course in civil life was somewhat the same. This table, compiled partly from data supplied by the Census Bureau, shows the dates when marked increases occurred in the number of deaths from pneumonia in cities and camps in various parts of the country. From the table it would appear that the increase in the incidence of pneumonia among the principal cities of the United States preceded the increased incidence among the Army camps. If this is so, it is to be inferred that the camps derived their infection not from one another but from their immediate environment.

TABLE 12.—MARKED INCREASES IN DEATHS FROM PNEUMONIA IN THE PRINCIPAL CITIES AND ARMY CAMPS IN THE UNITED STATES FOR THE PERIOD FROM SEPTEMBER 8 TO OCTOBER 25, INCLUSIVE

Date Week Ending	Atlantic Coast		North Central		Southeastern		Southwestern		Pacific Coast	
	Cities	Camps	Cities	Camps	Cities	Camps	Cities	Camps	Cities	Camps
Sept. 14	Boston									
Sept. 21	Lowell New York	Devens Dix								
Sept. 28	Cambridge Worcester Jersey City Philadelphia *Providence* *Washington*	Lee Upton Syracuse Humphreys	Pittsburgh Chicago Minneapolis							
Oct. 5	Baltimore Buffalo Fall River Newark Richmond Syracuse	Meade Hoboken Eustis Newport News	Cincinnati Indianapolis	Custer Funston Grant Sherman Taylor	*Birmingham*	Beauregard Sevier *Logan* Hancock Gordon	*Denver*	*Pike*	*Los Angeles*	
Oct. 12	Albany Rochester		Kansas City Louisville Milwaukee Omaha St. Paul St. Louis	Dodge	Atlanta New Orleans	Greene McClellan Wadsworth Jackson Johnston Greenleaf		Travis Bowie	*Oakland* Seattle	
Oct. 19	New Haven		Cleveland Columbus Dayton Toledo			Sheridan		MacArthur Cody	San Francisco Spokane *Portland*	Fremont Lewis

This table shows how the pandemic spread across the continent. Both cities and camps in the Atlantic Coast groups were included. The states of Massachusetts, New York, New Jersey, Maryland and Virginia were attacked first. The first record of the spread of the pandemic near this group was the increased pneumonia death rate at Pittsburgh, Chicago and Minneapolis, cities of the North Central group, during the week ended September 28.

During the following week (ended October 5) pronounced epidemics occurred in five of the Army camps of the North Central group (Custer, Funston, Grant, Sherman and Taylor). During this week epidemics were reported by both cities and camps in the Southeastern and Southwestern groups, and in the city of Los Angeles of the Pacific Coast group.

It was two weeks later (week ended October 19) that the camps of the Pacific Coast group reported the *first marked increase in deaths from pneumonia.*

Table 13 gives the number of deaths from pneumonia reported in forty-six cities from September 14 to November 2. It shows the rise and progress of the pneumonia, and, so far as that *disease is the shadow* of the influenza, it affords evidence of the case incidence of the whole pandemic of the larger cities. No reliable evidence of the prevalence of influenza in the cities exists. This statistical table is based on figures contained in a special report of the Bureau of the Census, Washington, D. C., on deaths from pneumonia, and appended to the regular weekly report of that bureau for the week ended Nov. 2, 1918.

The special report covers the eight weeks period from September 8 to November 2, inclusive. Marked increases in the incidence of pneumonia deaths in the different cities are indicated by the totals for the week being printed in boldface. A weekly incidence which is more than double the average weekly figure for not less than two weeks preceding (when these figures are available) is considered a marked increase in this memorandum.

COMPARISON WITH OTHER PANDEMICS

It is interesting to compare the present pandemic with others, but the comparison cannot be close. It is impossible to say how severe were some of those which are recorded in history for the reason that statistical data concerning them are meager and imperfect. It is said that in 1889-1890 no less than 25 per cent. of the population was attacked in London; 33 per cent. in Antwerp; 39 in Massachusetts, and 50 in Paris. In 1823-1833 about 40 per cent. of the population of Paris is believed to have been affected. In 1872, three quarters of the population of London and some German cities were supposed to have suffered. The records of earlier visitations are more obscure.

In the 1918 pandemic, about 20 per cent. of the soldiers in the camps were attacked. This seems rather a large proportion for the whole country or, indeed, for the cities, and yet it may not be far amiss. By the time the disease has finally disappeared, it will have spread somewhat beyond its present limit; and if the patients that recovered in the Army are added to those of the full pandemic, the proportion of the whole population affected during this year will be found to have been still greater.

The total number of deaths resulting from the present pandemic will never be known. Observers of pandemics in other years have pointed out that influenza is a more fatal disease than is commonly understood, the unsuspected excess being due chiefly to lung and heart complications that do not promptly manifest themselves. Thus, although the number of deaths directly attributed to influenza in England and Wales in 1890 was reported as 4,523 per million, the registrar general, by analysis of the vital statistics for the period, stated that the number of deaths directly or indirectly attributable was 27,074 per million, or nearly seven times the apparent rate. In London the general death rate was increased by more than 20 per cent., in Berlin by more than 60 per cent., and in Paris and Brussels by more than 100 per cent.

TABLE 13.—DEATHS FROM PNEUMONIA REPORTED BY THE PRINCIPAL CITIES OF THE UNITED STATES FOR THE PERIOD SEPT. 8 TO NOV. 2, 1918, INCLUSIVE

No records now available show that there has ever been so much immediately fatal pneumonia as in the present pandemic. If to the known deaths are added an allowance based on the registrar general's estimate quoted above, the magnitude of the catastrophe appears truly appalling. Both in and out of the camps there will have been fewer cases of influenza and far more deaths than the records indicate. The cases will be overestimated — the deaths will not all be told.

BARRACK LIFE AND RESPIRATORY DISEASE

SOME EPIDEMIOLOGIC OBSERVATIONS ON THE RECENT OUTBREAK OF INFLUENZA *

VICTOR G. HEISER, M.D.
NEW YORK

The influenza epidemic through which we are passing has been responsible for 17,000 deaths among our troops in this country, and the toll among the civil population already exceeds 200,000 lives. This is a far greater disaster than has befallen the United States in many decades. We have come to look on the war in Europe as one of the greatest destroyers of human life in the history of mankind. Yet in the brief space of a few weeks more deaths have been caused by an acute disease than have occurred on all the battlefields in any similar period, notwithstanding that millions on millions of soldiers have been involved.

Among the civil population of New York, 50 per cent. of all deaths occurred between the ages of 25 and 45. From figures obtained from Boston, Philadelphia, Baltimore and other sources, it can be predicted that similar percentages will probably obtain in many other communities. The deaths in cities among the sexes appear to be about equal, although there was a slight excess among females in Boston. Thus, 100,000 persons between the ages of 25 and 45 have succumbed to respiratory disease. This means that we have already lost among civilians 50,000 men in the prime of life. This is a serious drain on our man power.

Viewed from another standpoint, it is apparent that it is more dangerous to be a soldier in peaceful United States than to have been on the firing line in France. From the statistics so far available, the death rate in the military camps is higher than among the civil population, even in similar age groups. The mortality in New York and Chicago, for instance, shows that the death rate in the Army is more than double that of the civil population of the same age group. There is also the possibility that when allowances are made for the fact that defectives have been eliminated from the Army, and that these poor "risks" swell the civil death list, the corrected margin will be still further increased in favor of the civil population.

A study of the Students' Army Training Corps and of vocational students shows that as living conditions approach those in the Army, so does the death rate approach that of the Army. Further observation shows that with few exceptions the mortality rate from influenza and pneumonia bears a very close relationship to the number of persons housed and living under barrack conditions. That is, when large numbers of persons live, sleep and mess together in one room, the death rate is almost invariably higher than among similar groups living under civilian conditions. In other words, the more nearly the housing, eating and congregating conditions in the Students' Army Training Corps resembled those which obtain normally at colleges or such as exist in civil communities, the death rate was correspondingly lower. The death rate among college students living in their customary way was about the same as that of the towns in which they were located.

---

* The data assembled in this paper are based on reports to Nov. 9, 1918, but subsequent deaths are more likely to emphasize the difference between civil populations and "barrack" populations than otherwise.

Men in the military camps of the United States are housed in barracks with a capacity of from fifty to 150 men in a room. Assuming that the total number of troops did not reach over 1,500,000, and that 17,000 deaths have occurred, this gives a death rate of 11 per thousand for the period of the epidemic. For instance, in Boston, which is one of the cities hardest hit by the epidemic, 591 deaths are reported in the male age group of from 20 to 30. The United States Census Bureau estimates that in this age group there are 78,524 males. This would give a death rate of 7 per thousand. The death rate among all ages in Boston from the beginning of the epidemic until November 2 was 5 per thousand. Figures from Washington and Baltimore show that approximately the same proportion obtained. In the majority of Western cities the civil mortality has been very much lower than in the large Eastern cities. In Chicago the rate among the male age group of from 20 to 30 was 4 per thousand, or about a third of the Army rate. It will thus be seen that the death rate among the troops has been two or three times as great as that among civil populations of similar age groups. It is noteworthy that in many of the large Western cantonments the death rate was as high as in Eastern cantonments, and even higher, so that climatic influence does not explain why the Western cities suffered less than the Eastern cities.

TABLE 1.—DEATH RATES AMONG GROUPS OF INDIVIDUALS HOUSED UNDER BARRACK CONDITIONS

Organization	Population	Deaths	Rate per 1,000
Michigan Agricultural College	1,600	12	7.5
Wisconsin University vocational students:			
First group	600	6	10.0
Second group	550	6	10.9
Minnesota University:			
Fort Snelling group	4,985	54	10.8
Vocational group	4,000	72	18.0
Feebleminded institution, Orient, Ohio	600	35	58.3

The death rates at representative colleges where vocational students and the Students' Army Training Corps were housed in barracks are as follows: At the Michigan Agricultural College, which has 1,600 students, there were twelve deaths, or 7 per thousand. On the other hand, among 3,100 students at the University of Wisconsin, of whom only a small percentage were housed in barracks, the death rate was only 3.8 per thousand. In the same university, however, among 600 vocational students who were housed in approved Army barracks, there were six deaths, or a rate of 10 per thousand. The same experience was repeated at Wisconsin in a second group of vocational students. At the University of Minnesota we have the Fort Snelling group, which consists of the students of the university, the hospital attendants, and the guards, the great majority of whom live under barrack conditions. In this group of 4,985 there were fifty-four deaths, or a rate of 10 per thousand. Among the 4,000 students in the vocational group at the University of Minnesota there were seventy-two deaths, or a rate of 18 per thousand. These men were housed in a big automobile building of many stories, and they slept many hundreds in a room. In accordance with previously accepted standards of cubic air space, floor area and ventilation, the conditions were good. At the institution for the feebleminded at Orient, Ohio, among 600 inmates who were housed from twenty-four to 160 in a room, there were thirty-five deaths, or a rate of 58 per thousand.

TABLE 2.—DEATH RATE AMONG SIMILAR AGE GROUPS IN CIVIL COMMUNITIES

City	Population Male Age Group 20 to 30	Deaths Influenza Pneumonia	Rate per Thousand
Philadelphia	176,137	1,558*	8.8
Baltimore	59,965	461*	7.7
Boston	78,524	591†	7.5
New York	573,749	2,420*	4.2
Chicago	259,668	1,035*	4.0
Milwaukee	56,685	61*	1.1
Army	1,500,000	17,000	11.0

* Number estimated from United States census returns up to Nov. 9, 1918.

† Boston City Health Department, up to Nov. 2, 1918.

It is proper to mention that there were many Students' Army Training Corps at a number of the colleges where a large percentage of the students were housed in barracks, and either no deaths occurred or there was a very small percentage. But it is also true that in such instances pneumonia was usually not introduced. Similar conditions, of course, obtained among the Army camps. The rate varied from the very low rate at Camp Wheeler, for instance, to camps like Sherman, where the rate reached 30 per thousand, so that the conditions of comparison between the military and the civilian population in this respect still remains the same.

From the accompanying tables the lower rate among civilians will at once be apparent. It has long been recognized that quartering men in barracks involves considerable risk of a high mortality from respiratory diseases. Classical examples are those among the men quartered in barracks in Panama and among the miners similarly housed in South Africa. The 10,000 or more deaths that occurred from pneumonia among our troops last winter is further evidence. The high mortality rate in the Great Lakes Training Station furnishes another excellent example. Experience among the members of the Students' Army Training Corps who were quartered in barracks or under semi-barrack conditions in the recent epidemic of influenza shows a higher death rate. It is most interesting to observe that these high death rates occurred in barracks where the cubic air capacity and the square floor area approximated the standard set for approved barracks, namely, a minimum of 500 cubic feet of air space and 50 square feet of superficial floor area per person, and that on the whole the ventilation was good.

TABLE 3.—DEATHS AMONG ALL AGES IN A NUMBER OF TYPICAL CITIES

City	Population	Deaths* Influenza Pneumonia	Rate per Thousand
Milwaukee	453,381	614	1.4
Indianapolis	289,577	427	1.5
Los Angeles	568,495	1,214	2.1
Louisville	242,707	610	2.5
New York	5,737,492	19,357	3.4
Providence	263,613	994	3.8
Boston	785,245	4,355	5.5
Baltimore	599,653	3,685	6.1
Philadelphia	1,761,371	12,665	7.2

* United States Census Reports up to November 9, 1918.

It is my purpose in this paper to note the mortality rates among groups of peoples housed under different conditions. No explanation will be attempted as to why death rates are higher among persons housed in barracks. However, it may do no harm to point out that experience based on laboratory investigations in our Army hospitals shows that in large wards the bacterial flora in the throats of the patients tended to become equal. In other words, when individuals were admitted who had different bacteria in their respiratory passages from those already in the ward, these organisms could soon be found in the others. The facts reveal a lower mortality among those housed one or two in a room. However, there may be other factors involved. For instance, in large Philippine prisons it has been the custom for the past ten years to disinfect the mess kits and hands before eating, because there was much reason to believe that it reduced the disease incidence.

In view of the present high state of infectivity of respiratory diseases, it is not unreasonable to assume that unless better housing conditions are provided wherever men live in barracks, a morbidity and mortality rate will obtain approaching that of the Army quartered in barracks last winter. One might well be led to ask, Is there a military or other emergency that would justify so great a sacrifice of life? It must be remembered that in addition to the humanitarian consideration, a heavy economic loss will be encountered. The college man in the Students' Army Training Corps, for instance, represents the period of life at which the greatest outlay has been made, with scarcely any return on the investment of education. Soldiers and workmen are great financial assets. But there is even a more serious factor to be considered. Men living in barracks are widely scattered throughout the United States, and many groups are in intimate relationship with our large, populous centers, to which they will, unless corrected, transmit dangerous communicable diseases like pneumonia, cerebrospinal meningitis, septic sore throat, diphtheria and measles, thereby becoming a serious menace to the health of the civil community. Thus, much preventable and unnecessary disease would be caused. It would seem well to consider plans for "debarracking" aggregations of men throughout the United States. As matters stand, those responsible for retaining men in barracks are assuming a heavy responsibility.

SUMMARY

1. Experience in this country since the war began has shown that soldiers who live under barrack conditions have a high morbidity and a particularly high mortality rate from respiratory disease.
2. The mortality rate among the Students' Army Training Corps in the recent outbreak of so-called influenza was higher than among students who lived under prewar conditions.
3. Civilians throughout the country had a much lower mortality rate than soldiers in cantonments and students in barracks at colleges and universities.
4. Other conditions being equal, the mortality was higher among groups of men who slept many in a room. There may have been other factors responsible than sleeping in the same room, as, for instance, infection through close contact at meals, infected mess kits and hand infections.
5. The high infectivity from respiratory disease at the present time makes it justifiable to require men to live under barrack conditions only in cases of extreme emergency.
6. Patients with different respiratory infections should not be quartered in the same ward or room, even in the presence of heretofore accepted standards for ventilation. If emergency conditions make such a course necessary, patients and attendants should when practicable wear approved masks or be otherwise protected.
7. Finally, sanitary art has not arrived at the point at which it can adequately safeguard the lives of men against respiratory disease who live under barrack conditions.

MUSTARD (YELLOW CROSS) BURNS

LEONARD D. FRESCOLN, M.D. (PHILADELPHIA)
Major, M. C., U. S. Army
FRANCE

Recent attacks have shown that instead of the former gas cloud offensives being employed, the so-called "mustard gas" shells have been used to play an important part in annoying the enemy. A burn of either the first or the second degree with some of the retained irritant is produced. The liquid may be splashed on the part or the vapor reach the skin sufficiently to produce a redness and some hemorrhage. The real burn may be suspected but not appear until twenty-four hours.

This irritant is called in German literature by several names, and "yperite," or dichlor-ethyl-sulphid chemically. It vaporizes on the explosion of the shell and then does the damage to those exposed, but its effect is not much appreciated before four hours. Besides the skin manifestations there may be, after a day, vomiting, cough, hoarseness and pain. The eruption itself may appear as punctate, rose-red areas, simulating a vesicular eczema, or at times desquamation. The fluid contents may coagulate and become infected. Moreover, the fluid sometimes spreads, and there can be quite a large area of burning and itching. Ulcers sometimes form and persist for six weeks. As a rule, pigmentary changes result. Only rarely is there loss of hair; this is seen best in the lower animals.

Some individuals seem more susceptible to its severity than others. Occasionally a physician handling the patients will be infected from the contents of the blebs. Those who are sweating profusely are liable to suffer a nettle rash eruption. Furunculosis results at times. The chemical seems to be absorbed through the layers of the skin. A splash into the eye may destroy this organ, though this has occurred rarely, but the fumes merely inflame and at most cause linear scratches on the cornea made visible by 1 per cent. fluorescein.

Two things are important in combating this cruel weapon: First, to recognize early any suspicion of the irritant and protect against it, and second, to administer on the field first aid correction and prevent involvement of others. One should insist on the immediate application of masks, covering well exposed parts, and withdrawal from the immediate neighborhood, remembering to discard as much as possible all things contaminated. The best way to alleviate parts attacked is to have ready a 2 per cent. sodium bicarbonate solution for the eyes and throat and a 2 per cent. chlorinated lime preparation for the skin and neutralize quickly, for this cannot be used efficiently later any more than an acid burn can be thus treated long afterward. In fact, the lime will later irritate the exposed derm. Aromatic spirits of ammonia may be inhaled, or 2 per cent. sodium thiosulphate and 0.5 per cent. sodium bicarbonate (German method) used as a spray for treating the upper respiratory tract. Complete rest should be given in marked cases as in other gas cases, and plenty of ventilation provided. If severely affected patients have been brought from dirty holes or trenches, I would advise a dose of tetanus antitoxin. In emergencies a lather of soap is placed on exposed parts of the body. Further treatment is that of an ordinary burn, the aseptic opening of blebs, care being taken not to allow the contents to touch other parts of the skin. Five per cent. sterile boric acid ointment is a good dressing covered by sterile gauze pad and bandage, or 10 per cent. sodium bicarbonate ointment. The eyes are washed with solution of boric acid and covered, and the lids protected for some time with bland yellow mercuric oxid ointment and fear of further injury dispelled. Later dusting powder of bismuth and zinc oxid, or of zinc stearate will prove satisfactory for abraded skin areas.

Dugouts and holes where a person is likely to sit are to be suspected and carefully evacuated by an attendant wearing oil canvas protection. Then chlorinated lime is scattered in places suspected. Articles of salvage and waste should always be held under suspicion of being contaminated. The clothing is soaked in several changes of water at 70 C. Instead of strong alkaline remedies, potassium permanganate, 0.05 per cent. solution, is recommended, or a 0.1 per cent. zinc chlorid, and between the fingers or folds of the scrotum, a weak silver nitrate solution. In advanced respiratory cases, oxygen inhalations are used.

Owing to the censorship, the photographic reproduction of many interesting cases is not permissible. These cases should be given careful attention, and after treatment one need not necessarily excuse patients with mild skin burns from duty.

EFFECTS OF THE INJECTION OF EPINEPHRIN IN SOLDIERS WITH "IRRITABLE HEART"

PRELIMINARY NOTE

FRANCIS W. PEABODY, M.D. (Cambridge, Mass.)
Major, M. C., U. S. Army
HARRY D. CLOUGH, M.D. (Providence, R. I.)
CYRUS C. STURGIS, M.D. (Pendleton, Ore.)
JOSEPH T. WEARN, M.D. (Boston)
First Lieutenants, M. C., U. S. Army
and
EDNA H. TOMPKINS
LAKEWOOD, N. J.

On account of the general interest that has been aroused in the clinical syndrome originally described by Da Costa as the "irritable heart of soldiers," it has seemed to be advisable to present in the form of a preliminary note the observations recorded herein. No broad conclusions are as yet drawn from them. The investigations are being continued, and they will be published in detail later, when the work on the various sections is completed.

PHYSIOLOGIC ACTION OF EPINEPHRIN

In spite of the large amount of clinical and experimental work that has been done on the physiologic action of epinephrin, and on the effect of its injection into the human and animal body, our knowledge of the subject is still very far from complete. There are, indeed, not a few points on which rather fundamental differences of opinion exist among competent investigators. Nevertheless, one fact appears to be quite definitely established, and from the standpoint of the present study this is perhaps sufficient to provide a basis on which to interpret the results. Broadly speaking, epinephrin acts as a stimulant to the sympathetic nervous system.

METHOD

The method adopted was that devised by Goetsch[1] and used by him especially in the study of thyroid disease. The patient lies quietly on a bed for at least an hour. Observations are then made on the systolic and diastolic blood pressure, pulse rate and respiration rate. Notes are also made on the presence of and degree of tremor, sweating, temperature of hands, pulsation of vessels (peripheral and abdominal), and general nervousness. When the blood pressure, pulse and respiration rates are found to be constant for several observations made at five-minute intervals, an injection of 0.5 c.c. of 1 : 1,000 solution of epinephrin (Parke, Davis & Co. adrenalin tablets freshly prepared) is made into the deltoid muscle. Records are then taken of the systolic and diastolic blood pressure, pulse and respiration rates every two minutes for ten minutes; then every five minutes for one hour, and then every ten minutes for half an hour. At the same time any changes in the symptoms mentioned, or the appearance of new symptoms, is noted. The dosage of epinephrin appears to be well chosen. A large dose would probably produce symptoms in almost every one, but this small amount makes possible the differentiation of a group of persons who may be regarded as hypersusceptible to epinephrin.

A positive reaction to the epinephrin injection consists in the production of a rise in the systolic blood pressure or of the pulse rate of over ten or fifteen points, accompanied by the production of rather typical symptoms, such as flushing, sweating, increased vascular pulsation, increased tremor of the hands and often of the arms, restlessness, and more or less marked general nervousness. The blood pressure may rise 30 or 40 mm. in marked positive cases, and the tendency of the pulse is to follow the systolic blood pressure. Pulse pressure is characteristically increased. Respiration usually increases in depth but not in rate. A moderate rise of blood pressure or pulse rate alone, without the characteristic increase in symptoms, is not regarded as constituting a positive reaction. Slight symptoms may appear in many instances in which a definite reaction is not obtained, and it takes a little experience with positive and negative results to be able to differentiate between the two. The reaction usually begins about twelve minutes after the injection of epinephrin, reaches its climax on the average in thirty-two minutes and is finished in a little over an hour.

CONTROL AND CLINICAL OBSERVATIONS

Some difficulty was found in selecting suitable subjects for control observations. Persons merely in good health while leading a more or less normal life could hardly be used for comparison with a group of men who had developed symptoms while under nervous and physical strain, for one could never be sure exactly how the controls themselves would survive under similar circumstances. Thus, for instance, the hospital medical detachment could not be used, as it contains many men who are assigned to it for the very reason that they are not fitted for the strain of full duty. It seemed necessary, therefore, to look for controls in an organization that had been doing full duty for a considerable period. Such men were found in the 109th Sanitary Train, then at Camp Dix. This had been in active training for nearly two years, and the men were in the finest physical condition. With the permission of the division surgeon and the commanding officer, epinephrin tests were made on twenty-seven men picked at random from a group volunteering for the purpose. One man gave a slight suggestive reaction, but in no instance was a typical reaction observed.

---

[1] Goetsch: Personal communication to the authors.

The clinical observations to be reported at present comprise those made on a group of sixty-five soldiers representing what may be termed the "constitutionally inferior" type of patient with "irritable heart." Those in whom the symptoms date from a recent infection, and those in whom symptoms developed only after some unusual physical or nervous strain after they had done full duty in training for a considerable period, are excluded. There remains a group of patients giving a clinical picture which is essentially the same in all the cases. It is, moreover, a type of man that is being seen very commonly in the camps in this country at the present time. These patients usually give a history of being "weak" or "easily exhausted" for many years; of having always "favored" themselves, and having avoided "overexertion" often at the solicitation of relatives or on the advice of a physician. Often they have been told they have a "weak heart." They have always done "light" work, have usually "lost much time," and are fairly well contented in a low economic grade. Among their symptoms are nervousness, fainting, vertigo, dyspnea, palpitation and precordial pain on slight exertion. Perhaps the most fundamental symptom, however, is a tendency to become fatigued easily. They have little ambition or "push," and are usually without much self-confidence. They are often introspective or neurotic, and try to evade physical and mental exertion. In civil life many of them belong to the vague group of neurasthenics, but they get along fairly well for they are able to adapt their lives to themselves. When they are brought into the Army they are forced to adapt themselves to a wholly abnormal life—a life of physical and nervous strain—and they fail. Perhaps the most characteristic feature of the whole group is the fact that while the length of their Army service may be months, the period they have done full duty is usually measured by days. Under the strain of drill and hikes they fall out and report to the hospital with symptoms resembling those seen in organic heart disease. In spite of the fact that on physical examination, except for an instability of rate, the heart is normal, they are usually classed among cardiac patients, and the diagnosis "cardiac disease, functional" is made.

Of sixty-five patients in this group, the epinephrin test was positive in thirty-nine (60 per cent.), doubtful or suggestive in six (10 per cent.), and negative in nineteen (30 per cent.). In considering these results one must accept the fact that the clinical group dealt with does not necessarily represent one single clinical entity. There is no reason to suppose the etiology of the symptoms is in all cases the same. It is distinctly interesting, therefore, that so large a proportion should be hypersensitive to epinephrin, and one should at least consider carefully whether an unusually excitable sympathetic nervous system may not play a part in determining their condition. When one compares this group with its positive epinephrin reaction to the group of thoroughly trained soldiers in whom no definite reactions were obtained, the contrast is certainly striking.

BASAL METABOLISM

The effect of the injection of epinephrin on the basal metabolism has been studied in persons giving a positive reaction, and in others in whom no reaction was obtained. The expired air was collected for the periods of nine or ten minutes in a large Tissot spirometer, analyzed, and the heat production calculated from the oxygen consumption and respiratory quotient. The results were compared with the standards given by Du Bois and his associates at the Russell Sage Institute of Pathology. One or two periods were taken before the injection of epinephrin, and one, two or three periods following the injection. In six patients who did not give reactions to epinephrin, there was a rise of metabolism after the injection of epinephrin amounting to between 3 and 11 per cent. Following this there was a fall in metabolism to from 3 to 11 per cent. below the initial normal figure. In sixteen cases showing a positive reaction to epinephrin the rise in metabolism amounted to from 15 to 32 per cent. This was followed after the reaction was over by a fall in metabolism to a point from 3 to 5 per cent. below the initial metabolism before the epinephrin was injected. An injection of salt solution produced no increase in the metabolism in a patient who subsequently showed a rise of 29 per cent. after the injection of epinephrin. The epinephrin caused an increase in the metabolism of more than 20 per cent. in thirteen of the sixteen cases. Epinephrin seems to cause a rapid rise in metabolism, reaching its maximum at the height of the reaction and then falling off rather quickly. The rise in metabolism closely parallels the rise in blood pressure. In the majority the increase of metabolism was associated with a rise in the respiratory quotient.

BLOOD SUGAR DETERMINATIONS

In fifteen cases—seven sensitive to epinephrin and eight negative—blood sugar determinations were made. Three specimens of blood were obtained for analysis, one before the injection of epinephrin, a second from thirty to forty minutes later, an endeavor being made to obtain the blood at the height of the reaction if the patient was epinephrin-sensitive, and a third an hour and a half after the giving of the epinephrin. In each patient following the epinephrin injection the blood sugar was increased, the epinephrin-sensitive cases showing a greater increase than the negatives. The results so far are: Average blood sugar rise in seven epinephrin-sensitive cases, 0.044 per cent.; average blood sugar rise in eight epinephrin-negative cases, 0.028 per cent.

ELECTROCARDIOGRAMS

Electrocardiograms were taken in twelve cases before the injection of epinephrin, at approximately the height of the reaction and after the reaction was finished. At the height, ten of twelve patients noted symptoms, such as dizziness, blurred vision, palpitation and precordial pain, that bore a close resemblance to the symptoms prominent in their histories. The most constant change found in the electrocardiograms was a slight decrease of the height of the T-wave. This always occurred in one lead, usually in two leads, and sometimes in all three. It was most marked in the second lead. In individual cases other abnormalities were seen, as increase of a sinus arryhthmia; inversion of the P-wave; prolongation of the P-R interval, and partial heart block; inversion of the T-wave, and the production of ventricular extrasystoles.

SATURDAY, DECEMBER 7, 1918

A SPANISH EDITION OF THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

In a communication to the Editor last March, President George E. Vincent of the Rockefeller Foundation suggested that the publication in Spanish of The Journal of the American Medical Association—thus making it available to our colleagues in Central and South America and elsewhere—would be a great achievement, for promoting both scientific medicine and better international relations. The subject was brought before the Board of Trustees of the American Medical Association at the meeting in Chicago last June. The Board gave the matter very favorable preliminary consideration, and ordered that an investigation be made and further facts presented, so that final action might be taken at a later meeting. The matter was again considered at a recent meeting of the Board, with the result that the publication of a Spanish edition of The Journal was authorized.

The question of establishing closer relationship with the Central and South American republics, Mexico, Cuba, the Philippine Islands, etc., has long been regarded as an important one. The Pan-American Union has been developing this spirit of friendship and cooperation for many years. While business and commercial relations have been developing very rapidly, thus far the scientific men of the United States do not seem to have appreciated the opportunities and the benefits that would result through mutual exchange of views and ideas and of the results of research and investigation. The medical problems of Latin America always have been essentially the same as ours; we have only to recall the comparatively recent epoch-making work of Finlay, Reed, Gorgas, Guiteras, Liceaga and Cruz on yellow fever, of Ashford on hookworm disease, and of Strong on verruca peruana to show how identical are our interests in this field, and how much is to be gained by making each other acquainted with what we are doing and what we have already done. Our colleagues to the south of us have been looking more to France and Germany than to this country for their medical literature, and their medical students were more likely to go to those countries than to this for their undergraduate and postgraduate work.

Some weeks ago letters were sent to about two thousand physicians in Central and South America, outlining the proposition of publishing a Spanish edition of The Journal, and asking their opinion as to whether such a journal would be welcome. There has not been time for replies except from Central America and the northern parts of South America; but all of these replies have been enthusiastically favorable to the proposition.

Preparations are now being made for the publication of the initial number early in January. For the time being the Spanish edition will be issued semimonthly. It is proposed to include in it practically all of the scientific matter that appears in The Journal. Original articles and editorials that are of local or very ephemeral interest will not be included, nor will it include the medical news listed under states, marriages, deaths or matter of this character. In a word, everything that may be regarded as of general interest to the new readers, and especially all that is of permanent value, including, of course, the abstracts, Current Medical Literature, and foreign letters, will appear in the Spanish edition.

It needs no prophet to forecast the fact that the relations, always close, between the democracies of North and South America will with every succeeding day become closer and more advantageous on both sides. The better we know each other, the better friends we shall be. Nowhere can this friendship and close relationship be more fruitful than in the field of science, and especially in medical science. It is in this spirit of cooperation and confraternity that the American Medical Association is entering on this enterprise. It may be unnecessary to say that *no* financial gain is hoped for from this publication. If after several years it pays its own way, it will be doing all that can now be expected of it. Rather, it may be said that the enterprise is begun wholly with the spirit of fostering true internationalism and with purely altruistic motives.

THE FUTURE OF THE MEDICAL PROFESSION

Scarcely have we had time to realize that the great war is over when the numerous after-the-war problems present themselves. Reconstruction seems to be the word on every one's tongue, and the term is applied to almost every phase of human activity. There is reconstruction of the wounded, not only in a physical sense, but also in the sense of reeducating the partially disabled along lines that will enable them to become self-supporting; reconstruction of the industries to meet the new problems of finance, transportation, labor, foreign markets, etc.; in fact, conditions have changed so that readjustments along many lines have become necessary. Nor is the reconstruction idea limited to certain activities, for in some countries the fundamental principles of social existence are rapidly undergoing reconstruction. There is so much upheaval going on throughout the world that it is not surprising that the medical profession has received some attention.

The future of the medical profession in England was discussed by Sir Bertrand Dawson in the last Cavendish lecture.[1] It appears that the position of the physician in England is far from being an enviable one and that certain reforms are greatly needed. The physician is overworked and underpaid, and the influence of the profession as a whole in public affairs seems to be practically nil, even when they relate to matters with which the medical man should be the most competent to advise. This is indeed unfortunate, not only for the physician, but also for the community. The present condition of the profession is not the result of the war but the outgrowth of many antecedent conditions, not the least among which is the national health insurance law.

Many physicians who are doing panel work under this law, even with hard work, are unable to earn more than £30 ($150) net a year. While it is admitted that the panels might be made larger and thus yield greater return, this simply reduces the practice of medicine to a question of physical endurance, without regard for brains and ability.

There is much food for thought in this situation for those who without due consideration are urging state health insurance in this country. Dawson's hope for the future of the profession in England lies in a modified form of state medicine. It contemplates the establishment and maintenance by the state of health centers, a health center to consist of a hospital with its out department, social service, etc. The physicians connected with each health center would receive a salary from the state, in return for which they would render medical service at state expense to those of the community who, under the regulations, are entitled to such service. The physicians would not be expected to give their whole time to state work, but would be permitted to have pay patients in the hospital as well as outside, and to receive for their services as the circumstances of the patient may admit, or as their reputation and skill may command.

In certain larger communities there would be so-called "teaching hospitals," with a paid staff, some of the members of which are to be full time, others part time; the younger members of the profession may receive instruction at these institutions, and medical research therein is to be encouraged. The plan contemplates a minister of health, with a council of medical men forming a great state health department.

The general idea of a health center has merit, but the best method of establishing and maintaining it is open to argument, particularly as to the extent to which the state should contribute. The scheme as outlined by Dawson has for its purpose the betterment of the conditions under which the medical profession is laboring in England today. That the adoption of some such plan would be an improvement, at least for the time being, is perhaps correct. The chief criticism, however, which may be made of this scheme is that the betterment of the profession alone is considered; but no lasting improvement can be hoped for that does not take into consideration the community as a whole. It is a problem of society, not simply a problem of a class. The analysis of the deplorable conditions of the profession does not go deep enough into the causes, and unless the causes are recognized and remedied, little permanent improvement will result.

DEMOBILIZATION AND VENEREAL DISEASES

The prospect of demobilization of more than 4,000,000 troops presents a large sanitary problem, especially as regards the venereal diseases. The situation offers a unique opportunity for influencing the spread of these diseases in this country. If proper action can be taken so that every soldier with venereal disease can be rendered noninfectious before discharge from the Army, the future venereal disease condition of the country will be greatly benefited. If no successful effort can be carried out to render these men noninfectious before their demobilization, the result, on the contrary, must inevitably be a great increase in the incidence of these diseases. One of the greatest disasters of war is the spread of infections that occurs through the occupation of territory by troops, and even to a greater extent through the disbanding of troops at the close of war. Epidemics following wars have often caused far greater loss of life than have the actual casualties of war itself or diseases occurring among troops during the prosecution of war. This applies particularly to the venereal diseases.

It is clear, then, that a serious epidemic of venereal diseases may befall us if a thoroughgoing, vigorous policy is not pursued in demobilization. Fortunately, it would appear to be comparatively simple to outline a course of action which, successfully carried out, would minimize and probably eliminate this danger, and furthermore, would have an appreciable effect in diminishing the present incidence of venereal infections. The fundamental proposition is that soldiers should not be discharged from the Army as long as they are infectious with chancroid, syphilis or gonorrhea.

The problem of chancroid is a small one, since few cases of this condition or its sequelae occur that cannot be definitely rid of infectiousness in a few weeks.

The practical dangers of syphilis are from the chancre, from mucous patches in the mouth and about the genitals, and from condylomas. All of these can be disposed of in a few weeks under active treatment.

---

[1] Dawson, B.: The Future of the Medical Profession, Brit. Med. Jour., 1918, 2, 23, 56.

While there is always some danger of recurrence within the next few months, this danger rapidly diminishes as time elapses. In patients who have been treated vigorously with mercury or with mercury and arsphenamin, the danger from these lesions disappears in from four to eight weeks in most cases, and is almost eliminated within six months after the beginning of treatment. In active cases of syphilis, therefore, a great practical advantage would be gained by holding patients for two months, and their danger to the country would be practically eliminated by delaying their discharge for six months. Any remaining trace of danger could still further be reduced by impressing on uch patients the necessity for further treatment, h of course they should have for their own good.

he incidence of gonorrhea is so great, and its infection so insidious after the disease becomes chronic, that it presents the most important and the most difficult of these problems. There are, however, certain definite, well-recognized criteria by which the infected men may be judged to be free from subsequent danger of infectiousness. These criteria can be met by treatment in many cases in from three to six weeks, in most cases in from six to eight weeks, and the cases are rare that cannot be cleaned up by intelligent, vigorous treatment within six months. Patients with gonorrhea in the Army should not be discharged until they meet these criteria.[1]

The practical difficulties of the general problem are (1) the trouble and expense of holding the infected men while undergoing treatment before discharge, and (2) the danger of these men becoming marked in the minds of their civil acquaintances as being venereally infected by reason of the delay in their discharge. The former is of small importance compared to the great advantage for the civil population which this policy would involve. To send these men back to civil life with their infections uncured would be a sanitary crime. The second of these difficulties would not seem hard to obviate because of the relatively short time necessary to carry out this policy. The American Army from Europe cannot be disbanded in a week after it reaches our shores. Some men will have to be retained in service for a few months. The same facts apply to the men in the various domestic camps. It ought, then, to be possible to detain the venereally infected without disclosing the reason for so doing.

According to newspaper reports, Surgeon-General Ireland proposes to detain men with infectious diseases, including venereal diseases, in accordance with a general policy. It is greatly to be hoped that no considerations of expediency will be interjected to interfere with this enlightened policy.

THE PRODUCTION OF DRUG PLANTS IN THE UNITED STATES

In the early days of the European war this country was brought to a realization of the extent to which it had become dependent on foreign sources for the supply of crude drugs. Much was written about the efforts that should be made to avert the threatened drug famine by seeking unanticipated sources of supply as well as by prompt stimulation of the cultivation of medicinal plants. It was easy for the untutored propagandist to recall "the good old days" when home gardens not infrequently contained a variety of herbs that enjoyed popularity as healing agents and when the fields and forests were recognized as sources of plants of reputed medicinal value. Two or three years ago much was even said about the patriotic duty of growing drug plants.

The existence of a drug crisis after the summer of 1914 need no longer be dwelt on. Now that the prospect of peace permits an unbiased if not unhampered survey of the situation, the medical profession cannot fail to have a serious interest in our prospect and our duty regarding the production of drug plant crops. Two facts of direct import in the matter have been emphasized by an expert of the Bureau of Plant Industry in the United States Department of Agriculture.[1] Owing to the great development of foreign commerce, which made it possible to obtain supplies of most crude drugs from sources where the cost of production was less than in this country, drug cultivation has never become an important branch of agriculture in the United States. In recent years it has been confined chiefly to the production of relatively small crops of plants yielding volatile oils which are in demand for industrial purposes as well as for medicinal use. Furthermore, the problem of marketing drug plants has never been seriously considered here. There are hazards and uncertainties that might lead an enthusiast into early difficulties. Hence, as Stockberger warns, unless closely supervised by some central authority, any extensive movement to grow drugs might easily result in the production of far larger quantities than are needed. This would involve a useless expenditure of effort which might accomplish much good if exerted in other ways.

Out of the large number of plants that yield useful drugs, the list of those suitable for cultivation in this country is not large. Many of them demand tropical or semitropical conditions; others require much experimentation to transfer them from wild states to those of commercial cultivation in new environments. Like so many other problems raised by the war, that of the successful and profitable production of drug plants clearly indicates the need of expert advice and scientific consideration. Peppermint, spearmint, wormwood, wormseed and tansy are now grown commercially, chiefly as a source of volatile oils. Cannabis is produced in the Southern states. The experiments in camphor growing have encountered financial obstacles owing to the large outlays involved. Digitalis is sufficiently abundant as a wild plant in the Western states to allay all danger of a serious shortage. The American requirement of belladonna could easily be satisfied by the yield from 500 acres; and at least one fifth of this was harvested from cultivation in 1917. Recent attempts to produce henbane as a drug crop in this country have resulted in failure.

---

[1] The following test of cure of gonorrhea is taken from "The Venereal Diseases," American Medical Association, 1918, price 25 cents:

The man should take vigorous exercise on the day before the one on which the examination is to be made.

He should not urinate for two hours before the examination is made.

Examination should show the following findings:

1. He should have no urethral discharge, or at most a mucopurulent drop at the meatus should be obtained on stripping the penis.

2. If such a drop is found, it must be free from gonococci.

3. In the two glass test, both Glass 1 and Glass 2 must be clear and free from pus shreds. Epithelial shreds free from gonococci may be disregarded.

4. The secretion obtained by massage of the prostate and seminal vesicles must show no gonococci and few leukocytes.

5. Examination with a *bougie à boule* should demonstrate the absence of stricture.

[1] Stockberger, W. W.: Production of Drug Plant Crops in the United States, Yearbook, Dept. Agric., 1917, p. 169.

Perhaps the enforced restrictions of war-time shortage will have had the not undesirable effect of demonstrating that many of the drugs now in use can well be dispensed with. This will be in harmony with the efforts of the Council on Pharmacy and Chemistry of the American Medical Association, which has long insisted that "a considerable proportion of Pharmacopeial drugs and preparations are superfluous or worthless."[2] In the realm of desirable drug plants, haphazard methods of cultivation are quite as objectionable as is indiscriminate dispensing in the domain of therapy. For the production of a dependable supply of cultivated crude drugs of high quality, Stockberger writes, reliance must be placed on well-equipped growers who make the growing of drug plants a special industry, and who have the necessary experience in special methods of plant culture, acquaintance with trade requirements, and knowledge of the influence of time of collection and manner of preparation on the constituents of the drug on which its value depends. If developed along these lines, he adds, commercial drug growing in this country promises to become established on a sound basis for the future, when normal conditions return.

[2] Useful Drugs, a List of Drugs Selected to Supply the Demand for a Less Extensive Materia Medica, Chicago, American Medical Association, 1916.

Physical Education of the Citizen.—The physical education of its citizens has been left almost to chance by nearly all nations, although physical strength and fitness are very important factors in the work of every one. The play and work of their daily lives, together with a casual indulgence in sports on the part of a few, make up the physical training of the masses. Considering its great value to the nation, it would appear advisable to encourage athletic sports, to provide numerous leaders for the specific purpose of encouraging athletic contests and getting all, even the modest, into the fields, the golf links and tennis courts. The great value of universal military drill in strengthening the physique of the young adult is beyond question.—Dr. P. G. Nutting, *Scientific Monthly*, November, 1918.

Current Comment

THE CHANGING RÔLE OF SUGAR IN THE DIET

The promise of increasing allowances of sugar in the near future to the American housewife will be welcome news to many persons. This does not mean that the enforced war-time conservation of sugar has provoked any unpatriotic utterances or occasioned any serious hardship to our population. Every one who reads must realize, after some months of reduced allowance of this food commodity, that sugar is not an indispensable part of the diet. Equivalent substitutes have found a use so quickly and widely as to awaken admiration for the resourcefulness and intelligent culinary ingenuity of the American woman, who has contributed most effectively in many unheralded ways toward winning the war. The history of the place occupied by sugar has changed from decade to decade since the colonial period. After the Revolutionary War, the estimated consumption of sugar in the United States was only 7.5 pounds per capita. It rose slowly to 8.3 pounds in 1821-1825, and remained there for some time. In the year 1915 the per capita use amounted to 84 pounds. In other words, a century ago the people of this country consumed less than one-tenth as much sugar as they do now. A simple calculation shows that the prewar rate of use represented from one fifth to one seventh of the daily food need expressed in terms of calories, at a cost of 2 or 3 cents. It is evident, therefore, that the significance of sugar in the diet has changed from that of a mere flavoring matter a century ago to one of a staple. Indeed, before the war the retail cost of a year's supply for a family of average size was about $23 for sugar, $36 for flour, and $20 for potatoes, whereas the meat cost possibly $200. The promotion of sugar to such dietary prominence has been the result of the profound economic changes in our national life, through improvements in agricultural, mechanical, commercial and transport facilities. Sugar thus affords a striking illustration of how something at first only psychologically valuable may acquire a larger rôle in the daily regimen.

THE "ACRID PRINCIPLE" OF CERTAIN PLANTS

Among the numerous plants still included in the voluminous modern dispensatories of drugs, there are some that contain an irritant usually described as an "acrid principle." Phytolacca, or pokeroot, affords an illustration. A similar "principle" is believed to account for the acridity of certain plants that have not attained therapeutic dignity but are liable to come into contact with man in some accidental way. It is sometimes stated that these acrid principles are dissipated by drying and by heat. Brown and Anderson[1] of the Pharmacological Laboratory at the University of Minnesota have solved the acridity puzzle for a number of these cases. Being unable to isolate any volatile irritant, they turned their attention to mechanical factors. Plants like the Indian turnip, species of *Callocassia*, skunk cabbage and pokeroot contain abundant raphides of calcium oxalate. It is these needlelike crystal masses that produce the irritation referred to as acridity. Any procedure that disintegrates the acicular structures decreases their capacity to produce irritation. This may happen through boiling; hence the supposition of volatility of the irritant substance. The degree of so-called acridity is governed by the physical character of the crystals and the nature of the plant tissues in which they are embedded, those plants containing the long, very slender crystals being much more acrid than those in which the crystals are shorter and thicker. The penetration of the raphides of calcium oxalate in a mechanical way can produce a fiery and painful irritation.

DEMOBILIZATION AND PREMEDICAL EDUCATION

As noted elsewhere, the War Department has ordered the demobilization of all units of the Students' Army Training Corps, and the discharge of the student soldiers began Monday, December 2. This makes unnecessary the further continuance of the condensed course of premedical education which, as shown in The Journal,[1] was established two months ago as a war measure. Had the war lasted for another year, the continuance of the course as outlined would have been an interesting experiment. Since the necessity for it has been removed, however, its continuance would be at altogether too great a cost. It crowded into four quarters, of three months each, the work heretofore requiring six quarters, or eighteen months. Although the curriculum was planned to more than cover the sixty semester hours of credits (the credit measurement of two years of college work), that total was reached only by allowing a credit of about thirteen semester hours for military instruction and training—subjects for which previously no credit was allowed. The emergency schedule not only was a distinct retrogression from the standard of preliminary education generally adopted before the war began, but also, if continued, would be unfair to the students taking it. It would seriously limit their privileges of entering medical colleges, or, if accepted by the medical schools, it would prevent their securing licenses in the majority of states. While it is probable that the licensing boards would have been willing to make concessions if the war had continued, neither such concessions nor a retrogression in standards is justified now that the emergency has passed. The prewar standards have placed both premedical and medical education in this country on a par with those of other leading nations. America has been forced by the war to accept a larger responsibility than heretofore for world problems and policies; it should be in position also to wield a wider influence in medical education and practice. It is of extreme importance, therefore, that premedical college education shall be promptly restored to its prewar status.

Association News

NEW COUNCIL APPOINTMENTS

Filling Vacancies on Councils on Medical Education and on Health and Public Instruction

The President of the Association, Dr. Arthur Dean Bevan, has made the following appointments: on the Council on Medical Education, John M. Dodson, Chicago, vice H. D. Arnold, Boston, resigned; Isadore Dyer, New Orleans, vice H. Gideon Wells, Chicago, resigned; on the Council on Health and Public Instruction, Victor C. Vaughan, Ann Arbor, Mich., vice Ludvig Hektoen, Chicago, resigned. These appointments, in accordance with the By-Laws of the Association, fill the vacancies until the next annual session.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending November 29, there were in the Medical Corps 31,197 officers, an increase of thirty-nine over the previous week. This personnel includes three major-generals, six brigadier-generals, 200 colonels, 433 lieutenant-colonels, 2,357 majors, 9,986 captains and 18,212 lieutenants. There were in active service 30,408, an increase of sixty-nine over the previous week. Discharges to date include 2,855 officers.

European Red Cross Survey

It is announced by the American Red Cross that Major Homer Folks, formerly head of the New York State Charities Aid Association, who has been with the American Red Cross abroad since July, 1917, has been promoted to lieutenant-colonel and has been made chairman of a special mission to make a survey of the European countries in which the Red Cross is operating on which to base a comprehensive program of reconstruction. It is believed that through the rapidly changing conditions in those countries since the signing of the armistice an even larger demand may be made on the Red Cross. Investigations have already been made in Italy, and the Balkan countries will be next visited. The survey is to include Turkey, Armenia and Palestine.

Students' Army Training Corps Demobilized

On November 26 a telegram was sent to the presidents of all institutions having units of the Students' Army Training Corps, as follows:

> "Commanding Officers of all units of S. A. T. C. both Sections A and B have been directed to demobilize and discharge the men commencing week of December first, with a view to completion of discharge by December twenty-first. Secretary of War has directed this Committee to arrange adjustments under contracts between institutions and War Department concerning which you will be advised. Letter follows."

The letter referred to confirmed the telegram and stated that adjustments would be handled by the business department of the committee in accordance with a line of procedure which is now being determined. It requested that no arrangement be made for the salvage or disposal of barracks, equipment, etc., pending receipt of information from the business department.

Demobilization of Medical Officers

We are informed that the Surgeon-General of the Army has requested the honorable discharge of all officers over 50 years of age with a view to enabling men well along in life to return to their homes and to take up their practice or other work with as little delay as possible. This step is taken with the belief that the older men should have the advantage of an early discharge in order that the work of recovering their practice and reestablishing themselves in their civil capacities may be less difficult. In taking this action the Surgeon-General wishes it to be understood that the work and service of these men in the department have been greatly appreciated, as well as the substantial sacrifice which they have made in entering the service, the spirit which they have exhibited in tendering their services to the country in its time of need, and the satisfactory performance of the duties which have been assigned to them.

At the same time the Surgeon-General has requested the discharge of all officers with a personal rating lower than 55 on the scale of 100.

After these two classes of officers have been discharged the Surgeon-General will adopt a most liberal policy in the demobilization of the remainder of the Medical Corps, and will give special consideration to the policy of discharging officers who are needed by the community or whose affairs in civil life are making insistent demands for their early return. The age, length of service, location in which the officer lives, etc., will be especially considered in returning officers to civil life.

To assist the Surgeon-General to determine his policy of demobilization, a questionnaire is being circulated among the officers and it will be the policy of the department to take such action as will most nearly coincide with the interests and expressed desire of the officer. The questionnaire which has been circulated among officers is as follows:

From: The Surgeon-General

Subject: Demobilization of officers of the Medical Department.

1. I am directed by the Surgeon-General to advise you that the present plans for the demobilization of officers of the Medical Department holding temporary commissions and who hold no Regular Army commissions, contemplate the division of such officers of the Medical Department into four clases:

First: those desiring immediate and complete release by way of honorable discharge;

Second: those desiring immediate release from active service and reappointment in the Officers' Reserve Corps, inactive;

Third: those who desire to remain on duty under their present commissions as long as their services are required;

Fourth: those desiring appointment in the Regular Army and who are considered eligible for such appointment.

2. Under existing law the maximum age limit for appointment in the Medical Corps of the Regular Army is 32 years, Dental Corps, Regular Army, 32 years and Veterinary Corps, Regular Army, 27 years. There is no provision of law for Reserve Commissions in the Sanitary Corps.

3. The Surgeon-General requests that you advise the personnel division of this office immediately in which of the above classes you wish to be placed.

(Signed) C. R. Darnall,
Colonel, Medical Corps, U. S. A., Executive Officer.

In discharging officers the following individual records must be made and transmitted to the office of the Adjutant-General: copy of authority for discharge or separation from active service, report of physical examination, appendix to file record card and qualification card.

The following officers will not be discharged under the provisions of special instructions which have been issued: (*a*) officers holding commissions in the regular Army either on the active list or retired list; (*b*) officers under arrest on charges, or serving sentence of general court martial; (*c*) officers having had money or property accountability, and who have not clearance therefrom; (*d*) officers on sick report or in hospital; (*e*) officers who for exceptional reasons cannot be spared, or who in the opinion of the commanding officer should not be discharged at this time.

We are informed that it is the intention to issue Reserve Corps commissions in general to those officers who have served with credit to themselves in the war, and who desire such commissions.

Weekly Bulletin No. 29, American Expeditionary Forces

The following paragraphs are taken from Weekly Bulletin No. 29, Oct. 28, 1918, issued for circulation among American medical officers in France:

SECONDARY PNEUMONIA WITH INFLUENZA

From all sources, French, English, Swiss, Spanish, throughout the American Expeditionary Forces, and from our cantonments and civil health departments at home, the opinion appears to be unanimous that the respiratory infection now epidemic is due to, or at least the great majority of the cases are accompanied by, the influenza bacillus, which is easily and commonly found in the early stages or onset of the infection, and may be found in lungs, blood and cerebrospinal fluid. Great interest is attached to the incidence of the main, if not the only, serious complication, namely, the pneumonia, sometimes almost a sharply marked lobar involvement, oftener a disseminated patchy or bronchopneumonia.

A striking relationship is shown between the percentage of complicating pneumonias and the mortality from them, and the lack of resistance from one or other cause and the sanitation and hygiene of the different groups reported on. On shipboard with almost intolerable conditions of exposure, fatigue, anxiety, ill nourishment, poor ventilation and close contact, we have as high as 50 per cent. of bronchopneumonia, and of these cases as many as 50 per cent. die within a week of the onset of the disease. In one of the Army corps in active operations we had, in spite of fairly extensive prevalence of influenza, only 20 deaths from pneumonia in three months. In one of the large regions of France where there were many of the younger classes of the French military in barracks undergoing training, pneumonia developed in as high as 33 per cent. of the cases, the percentage of deaths being from 25 to 40 per cent. In a group of 500 cases of influenza at a camp hospital in the S. O. S., 6.45 per cent. developed pneumonia and of these 50 per cent. died.

With uniformity where resistance is high, as for instance, resulting from mature training and active outdoor military operations not beyond human endurance, where men have adequate clothing and hot food and can sleep in dry quarters, influenza is but a temporary inconvenience with insignificant mortality. Early recognition and hospital care prevents complications; segregation, by cubicle and mask, diminishes cross infection. Rest and symptomatic care and nursing under skilled internists diminishes the death rate.

The epidemic, which has lasted about two months since its return in the American Expeditionary Forces, is diminishing in almost all sections and among all troops, old and new arrivals. In Section 2 the reduction in cases has been 50 per cent. in the past week. The percentage of complicating pneumonias among cases in the American Expeditionary Forces has been from 9.3 to 10 per cent. and the total death rate from influenza and all pneumonias occurring during the period of the epidemic has been from 4.5 to 4.8 per cent. Reports from the French military and civil authorities show a mortality of from 5 to 8 per cent. The last convoys of transports arriving during the week with 28,898 men had 149 cases of influenza and pneumonia, and two deaths during the voyage, showing a vast improvement, one previous convoy having arrived with 24,000 troops and 233 deaths en route and another 311 among cases hospitalized after arrival at the base port.

We are beginning to get an increase in the primary lobar pneumonias and it behooves us to take advantage of the warning given us by the influenza and prepare to prevent pneumonia this winter by persistent and consistent measures to raise and maintain individual resistance by providing air, food, warm dry clothing, and by saving men where possible from exhaustion. Once a man is sick with a respiratory disease he must be treated with as much intelligent medical and efficient technic as is lavished on his fellow surgical sufferer who is guarded similarly against the ubiquitous streptococcus.

EPIDEMIC DISEASE REVIEW FOR THE WEEK

Influenza and pneumonia have during the past week diminished in all parts of the American Expeditionary Forces.

The present practice of hospitalizing and holding without transfer all respiratory diseases at once on establishing a diagnosis must be credited with the marked reduction in the number and severity of the complicating pneumonias after influenza. The almost universal adoption of some form of cubicle isolation of all respiratory tract infections in hospitals and the increasing use of nose and mouth masks for these patients on their way to hospitals and on hospital trains, and the protection of hospital personnel in the same way have also played a large part in reducing pneumonias and cross infections.

There has been a further fall in meningitis, 106 cases being reported as compared with 147 and 167, respectively, in the weeks ending October 20 and October 13, and of the cases reported in the past week just 50 per cent. are properly attributable to infection brought on transports.

Diphtheria again shows an increase. The cases are not grouped in any particular organization but are found (at least 67 of the 97 cases reported) among organizations engaged in active operations at the front. It would appear that the great difficulties in reaching men for medical observation of carrier and contact cases and the abundant opportunities for close contact among wounded men during evacuation from the front and from the evacuation hospitals are chiefly responsible for the increase in diphtheria.

Dysentery, measles, typhoid fever and scarlet fever show no significant change.

Weekly Bulletin No. 30

The following paragraphs are taken from Weekly Bulletin No. 30, Nov. 4, 1918, issued for circulation among American medical officers in France:

PREVENTIVE MEDICINE BY PUNGENT ADVICE IN A D. S. O. CIRCULAR OF 80TH DIVISION

"To all Medical Officers. 1. There are over five hundred (500) cases of diarrhea reported in the division. Laboratory examination and clinical study have proved the condition to be a catarrhal enteritis of undiscovered specific cause, and not dysentery. The disease has direct connection with faulty kitchen and mess sanitation, imperfect water sterilization, poor cooking and filthy latrines. In those organizations where food is handled and cooked properly, kitchens kept clean, bags rinsed, and latrines given required attention, there are few cases of diarrhea. Such condition exists in the —— Machine Gun Battalion.

2. In those organizations where there is not the required attention paid to these matters of sanitation the disease is prevalent. Such condition exists in the —— Battalion of the —— Infantry.

3. The matter resolves itself into medical responsibility, and the surgeon who neglects to meet this responsibility is directly responsible for the increased sickness in his command.

4. The mere making of recommendations to organization commanders, and telling people what to do, will not suffice. The surgeon must supervise the work at hand and see to it that sanitary requirements are carried out. If any difficulty is experienced in carrying out health measures properly, report will be made at once to the Division Surgeon, for action by the Commanding General.

5. The best treatment for the existing disease consists in early administration of castor oil, and dieting. Get the castor oil from the Medical Supply Officer. Merely requisitioning for it may not get it; go after it until you get it. Also ferret out the cases in the command so as to give them early treatment. Train the men to report to you promptly for any ailment. The serious cases of diarrhea are the ones not reporting to you until the disease has existed for four (4) or five (5) days or longer, and treatment has been delayed. Such cases generally require hospital treatment. Their service is lost, and when they are evacuated to corps hospitals, as frequently becomes necessary, the men are lost to the division.

6. Get an early breakfast, cut out that bridge game, and get on the job."

WEEKLY REPORT OF DISEASE

Meningitis has shown a gratifying reduction during the past week, 43 cases being reported as against 106 for the week previous. Scarlet fever, diphtheria and dysentery show similar reductions. The widespread prevalence of pneumonia and influenza continues, but there are signs of improvement not only in the military but also in the civil population. The mortality from pneumonia, primary, or complicating influenza, has been very high, in some sections exceeding 50 per cent. The same is true of bronchopneumonia.

The week ending October 18, 9,081 cases of influenza were admitted to hospitals in the American Expeditionary Forces and 10,985 the week ending October 25. Pneumonia, except bronchopneumonia, week ending October 18, 831; week ending October 25, 1,077; bronchopneumonia, week ending October 18, 492; week ending October 25, 853.

Weekly Bulletin No. 31

The following paragraphs are taken from Weekly Bulletin No. 31, Nov. 11, 1918, issued for circulation among American medical officers in France. This bulletin deals largely with the prevention of influenza and pneumonia among troops. In addition to the usual sanitary precautions, the following paragraphs are of interest:

Prevention of Influenza

WORK

When influenza is spreading rapidly in a command it is wise to remember that when men are overworked to the point of exhaustion they are rendered thereby extremely susceptible to infectious diseases. It is advisable, therefore, if military conditions at all permit, to ask that drill schedule and other work be slightly reduced until the epidemic is under control.

WHEN THE DISEASE HAS APPEARED: INSPECTION AND SEGREGATION

When cases of grippe have begun to appear the medical officer should attend roll call and rapidly inspect all the men every morning. This can be done with speed by walking down the line, observing men for signs of "colds in the head," coughing, sneezing, or red eyes, and asking a few questions. Suspicious men should be made to step out and be sent to the sick call, where temperatures should be taken.

Men with definite colds in the head, without temperatures, should be taken out of their billets and made to sleep in special barracks or billets, or other available space, with shelter halfs hung up so as to form screens between neighboring beds. If possible, they should be given an extra allowance of bed covering. They should be placed on light duty for a day or two. If no special quarters are available for such men, put them all together at one end of the barrack and separate this end from the rest of the barrack by hanging up blankets, or in some other way making a screen.

Men with temperatures but without pulmonary signs should be hospitalized in the infirmary or field hospital in special grippe wards. In such wards ample floor space and screening between beds should be attended to. If possible, light and loose gauze masks should be provided for patients and attendants. If the temperature continues without coming down for forty-eight hours, or if pulmonary signs develop, the patient should be evacuated promptly.

Of all men showing temperatures on first inspection careful chest examination should be made. If any signs pointing to extensive bronchitis or actual pulmonary involvement are found, the patient should be evacuated promptly.

EVACUATION

During evacuation grippe cases should not be placed in the same ambulances with wounded or with other sick. Remember that, in evacuating pneumonia, the greatest care must be taken to prevent their exerting themselves. Do not let them walk, or dress, or undress themselves. Keep them on their backs. Failure to observe this may make the difference between recovery and death.

HOSPITALIZATION

In evacuation and other hospitals, grippe cases must be placed in separate wards.

Cases developing pneumonia must be taken out of the grippe wards promptly and placed in separate pneumonia wards.

Beds must be screened one from the other.

Attendants must wear light gauze masks.

Sputum must be disinfected or burned.

Thermometers must be sterilized.

The report is also largely devoted to the epidemic of meningitis which developed in one of the camps, and a study of the cases of this epidemic.

The report concludes:

During the past week there has been a sharp increase in diphtheria, the cases having originated chiefly in the zone of combat in the advance section and thence evacuated to the base hospitals where but few new cases have develond. Dysentery and meningitis show further and marked reductions. Four cases of smallpox have been reported among incoming troops at base ports. Influenza continues to decrease although the incidence and case mortality of the complicating pneumonias continue high.

ORDERS TO OFFICERS OF THE MEDICAL CORPS, U. S. ARMY

Alabama

To Biltmore, N. C., for instruction, from Fort Oglethorpe, Capt. R. C. JONES, Mobile.

To Camp Bowie, Texas, base hospital, from Fort Oglethorpe, Lieut. C. H. MOORE, Birmingham.

To Camp Dodge, Iowa, base hospital, from Camp Grant, Lieut. A. L. GASTON, Ensley.

To Camp Travis, Texas, base hospital, from Fort Sill, Lieut. L. E. SORR[illegible]

To [illegible] of Pennsylvania, from University, Va., L[illegible] adsden.

To [illegible] -General's Office, from Washington, Major [illegible] SLEDGE, Mobile.

Arizona

To Newport News, Va., from New York, Capt. R. E. HERENDEEN, Bisbee.

The following order has been revoked: *To Camp Sheridan, Ala.*, base hospital, from Fort Oglethorpe, Lieut. E. B. THOMPSON, Benson.

Arkansas

To Fort Des Moines, Iowa, from Camp Dodge, Major L. THOMPSON, Hot Springs.

To Hoboken, N. J., from Panama Canal Department, Capt. D. GANN, Jr., Little Rock.

California

To Camp Jackson, S. C., base hospital, from Camp Cody, Lieut. E. H. CRABTREE, San Diego.

To Camp Leach, D. C., from Camp A. A. Humphreys, Lieut. B. J. LASSWELL, Quincy.

To Camp Logan, Texas, from Fort Oglethorpe, Capt. C. M. DePUY, Oakland.

To Camp Travis, Texas, base hospital, from Camp Kearney, Lieut. J. A. GUILFOIL, San Luis Obispo.

To Carlisle, Pa., from Camp Dix, Capt. C. L. McCLISH, Los Angeles.

To Detroit, Mich., from Fort Oglethorpe, Capt. M. P. BURNHAM, San Francisco.

To Fort Benjamin Harrison, Ind., base hospital, from Camp Pike, Capt. A. S. J. SMITH, San Jose.

To Fort Oglethorpe, base hospital, from Camp Fremont, Lieut. F. J. BRESLIN, San Francisco; from Camp Pike, Capt. J. A. JACKSON, San Diego; from San Francisco, Capt. D. A. CONRAD, Santa Barbara.

To Fort Riley, base hospital, from Fort Oglethorpe, Lieut. R. L. CRUM, Los Angeles.

To Hollywood, Calif., Los Angeles State and Normal School, from Fort McDowell, Capt. F. P. BRENDEL, San Francisco.

To Lakewood, N. J., from Fort Oglethorpe, Capt. A. F. HAMMAN, Long Beach.

To Los Angeles, Calif., as examiner, Capt. M. M. CLOUD, Los Angeles.

To Washington, D. C., Surgeon-General's Office, from Lake Charles, Major L. F. LUCKIE, Los Angeles; from Newport News, Major W. A. SAWYER, Berkeley.

To West Baden, Ind., from Camp Dodge, Major C. E. PHILLIPS, Los Angeles.

The following orders have been revoked: *To San Francisco, Calif.*, Leland Stanford University, for instruction, from Letterman General Hospital, Capts. W. C. BAKER, San Mateo; E. L. COTTRELL, Scotia; Lieut. L. DOZIER, Stockton.

Colorado

To Camp Lee, Va., from Camp A. A. Humphreys, Lieut. A. H. PETERS, Colorado Springs.

To Fort Riley, from Camp Zachary Taylor, Lieut. J. A. PHILLPOTT, Denver.

To West Baden, Ind., from Camp Dodge, Lieut. I. C. MIERLEY, Denver.

The following order has been revoked: *To Camp Sherman*, Chillicothe, Ohio, base hospital, for instruction, from Pittsburgh, Lieut. G. L. SHARP, Colorado Springs.

Connecticut

To Camp Travis, Texas, base hospital, from San Antonio, Lieut. F. M. SMITH, Willimantic.

To Camp Wheeler, Ga., base hospital, for instruction, from Fort Oglethorpe, Lieut. G. E. PORTER, Warehouse Point.

To Cooperstown, N. Y., from Fort Riley, Lieut. E. N. DEWITT, Bridgeport.

District of Columbia

To New Haven, Conn., from Fort Oglethorpe, Major R. D. ADAMS, Washington.

To Washington, D. C., Surgeon-General's Office, Colonel H. D. SNYDER, Major T. D. HURLEY. Washington Barracks, from Fort Oglethorpe, Lieut. W. J. G. THOMAS, Washington.

Florida

To Camp McClellan, Ala., from Auburn, Ala., Lieut. A. E. ACKER, Jacksonville.

To Camp Sherman, Ohio, base hospital, from Camp Beauregard, Capt. J. C. VINSON, Tampa.

Georgia

To Camp Wheeler, Ga., base hospital, *for instruction*, from Fort Oglethorpe, Lieut. P. C. QUARTERMAN, Valdosta.

To Fort McPherson, Ga., from Atlanta, Lieut. J. T. MOORE, Sycamore.

To Fort Oglethorpe, base hospital, from Camp Gordon, Capt. H. H. MALONE, Augusta.

To Walter Reed General Hospital, D. C., for instruction, and on completion *to Boston, Mass.*, from Camp Wheeler, Capt. O. L. MILLER, Atlanta.

The following order has been revoked: *To White Plains, N. Y.*, for instruction; from Fort McPherson, Capt. G. P. HUGULEY, Atlanta.

Illinois

To Baltimore, Md., Johns Hopkins Medical School, from New York, Capt. G. B. HASSIN, Chicago.

To Boston, Mass., for instruction, *from* Camp Devens, Lieut. J. L. WEBB, Chicago.

To Camp Cody, N. M., from Fort Bayard, Lieut. C. E. DUNCAN, McClure.

To Camp Custer, Mich., base hospital, *for instruction*, Lieut. P. H. WESSEL, Moline.

To Camp Devens, Mass., from Fort Oglethorpe, Lieut. G. M. LANDAU, Chicago.

To Camp Gordon, Ga., base *hospital*, for instruction, from Fort Oglethorpe, Capt. G. FITZPATRICK, Chicago.

To Camp Hancock, Ga., base hospital, from Boston, Capt. J. H. BACON, Peoria.

To Camp Lee, Va., base hospital, from Camp Custer, Capt. D. M. KEITH, Rockford.

To Camp Logan, Texas, from Fort Oglethorpe, Lieut. J. S. BERKOWITZ, Chicago. Base hospital, from Central Department, Major K. THEXTON, Chicago.

To Camp Meade, Md., from Fort Oglethorpe, Capt. J. V. WHITE, Auburn.

To Camp Travis, Texas, from Fort Riley, Capt. J. H. ELLINGSWORTH, East Moline. Base hospital, from Camp Pike, Lieut. J. T. O'NEILL, Joliet; from Fort Thomas, Lieut. G. H. ANDERSON, Chicago.

To Cape May, N. J., base hospital, from the Surgeon-General's Office, Lieut.-Col. P. P. SCHUYLER DOANE, Chicago.

To Everman, Texas, Barron Field, from Urbana, Lieut. R. F. KNOLL, Chicago.

To Fort Benjamin Harrison, Ind., base hospital, from Fort Riley, Lieut. D. F. PAUL, Chicago.

To Fort McPherson, Ga., from Camp Gordon, Lieut. C. A. JACOBSON, Chicago.

To Fort Oglethorpe, base *hospital*, from Camp Greene, Lieut. G. E. PFEIFFER, Chicago; from Camp *Jackson*, Lieut. H. SERED, Chicago; from Camp Shelby, Lieut. P. T. DIAMOND, Evanston. For instruction, from Chicago, Lieut. H. S. SULLIVAN, Chicago.

To Fort Riley, base hospital, from Fort Oglethorpe, Capt. H. H. SHEETS, Oregon; Lieuts. W. H. HOWARD, D. KLEMPTNER, Chicago.

To Fort Sheridan, Ill., from Camp Devens, Capt. N. S. DAVIS, III, Chicago; from Camp McClellan, Capt. W. H. GAMBILL, Centralia.

To Hampton, Va., Langley Field, from Morrison, Va., Lieut. C. H. REINHARDT, Chicago.

To Indianapolis, Ind., from Mineola, Major O. YARNELL, Decatur.

To Otisville, N. Y., from Camp Zachary Taylor, Capt. W. G. BAIN, Springfield.

To Plattsburg Barracks, N. Y., from Camp Travis, Capt. W. O. KROHN, Chicago.

To Rockefeller Institute for instruction in the treatment of infected wounds, *and on completion to Camp Upton, N. Y.*, base hospital, for instruction, from Fort Oglethorpe, Capt. W. H. GALLAND, Chicago.

To South Baltimore, Md., from Russel, Va., Capt. H. WOOD, Batchtown.

To Walter Reed General Hospital, D. C., for instruction, from Camp McClellan, Lieut. J. R. SHOLL, Peoria.

To Washington, D. C., from Chicago, Lieut.-Col. W. S. SHIELDS. Surgeon-General's Office, from Arcadia, Major R. H. BOLLING, Philadelphia.

To West Baden, Ind., from Camp Dodge, Capt. F. J. LESEMAN, Chicago. For instruction, from Fort Oglethorpe, Lieut. T. W. ROBERTS, Joppa.

The following orders have been revoked: *To Camp Sheridan, Ala.*, from Fort Oglethorpe, Lieut. G. W. WESTERMEIER, Carlinville; G. E. KNAPPENBERGER, Macomb. *To Hampton, Va.*, Langley Field, from Richmond, Va., Capt. R. R. TRUEBLOOD, Lawrenceville.

Indiana

To Camp Grant, Ill., from Camp Beauregard, Lieut. V. G. HURSEY, Legonier.

To Camp Lee, Va., from Camp A. A. Humphreys, Lieut. J. H. HAUCK, Terre Haute; from Fort Oglethorpe, Capt. C. E. GILLESPIE, Seymour.

To Camp Upton, N. Y., base hospital, Capt. H. B. COX, Morristown.

To East Norfolk, Mass., from Camp Greene, Capt. H. D. PURDUM, Sykesville.

To Fort Benjamin Harrison, Ind., for instruction, from Camp Shelby, Capt. H. G. FLEMING, Anderson.

To Fort Oglethorpe, base hospital, *from Fort McPherson*, Lieut. M. M. MORAN, Portland. For instruction, Capt. A. A. THOMAS, Linton.

To Fort Sam Houston, Texas, base hospital, from Camp Kearney, Capt. C. E. COTTINGHAM, Indianapolis.

To Fort Snelling, Minn., from Fort Oglethorpe, Capt. G. W. ANGLIN, Warsaw.

To report to the commanding general, Northeastern Department, from Plattsburg Barracks, Major G. L. GUTHRIE, Indianapolis.

To Rockefeller Institute for instruction in the treatment of infected wounds, and on completion *to Camp Sevier, S. C.*, base hospital, for instruction, from Fort Oglethorpe, Capt. E. A. BROWN, Indianapolis.

To West Baden, Ind., from Camp Jackson, Capt. J. A. MacDONALD, Indianapolis.

Iowa

To Camp Travis, Texas, base hospital, *from Camp Pike*, Lieut. C. C. LYTLE, Lansing.

To Camp Zachary Taylor, Ky., base hospital, from Nashville, Tenn., Capt. C. ASCHENBRENNER, Pella.

To Fort Benjamin Harrison, Ind., base hospital, from Fort Oglethorpe, Capt. T. B. LACEY, Glenwood.

To Fort Des Moines, Iowa, for instruction, from Fort Oglethorpe, Lieut. M. S. CORLETT, Westgate.

To Fort Oglethorpe, base *hospital*, from Otisville, Capt. W. L. HEARST, Cedar Falls.

To Fort Snelling, Minn., from Camp Grant, Capt. E. J. HARNAGEL, Des Moines; Lieut. W. H. REDMOND, Cedar Rapids.

To Lakewood, N. J., from Fort Oglethorpe, Lieut. J. O. MURPHY, Eldon.

To Rockefeller Institute for instruction in the treatment of infected wounds, and on completion *to Camp Meade, Md.*, base hospital, for instruction, from Fort Oglethorpe, Capt. F. LAMBACH, Davenport.

To Washington, D. C., Surgeon-General's Office, from Fort Riley, Major H. C. PARKER, Dubuque.

Kansas

To Camp Sherman, Ohio, base *hospital*, from Camp MacArthur, Capt. W. C. CHANEY, Independence.

To Camp Travis, Texas, base *hospital*, from Camp Pike, Lieut. G. A. KING, Maplehill.

To Denver, Colo., for instruction, from Fort Riley, Capt. C. J. McGEE, Leavenworth.

To Walter Reed General Hospital, D. C., from Fort Leavenworth, Lieut.-Col. F. N. CHILTON.

Kentucky

To Camp Lee, Va., from Camp A. A. Humphreys, Major G. C. LEACHMAN, Louisville.

To Detroit, Mich., from Camp *Jackson*, Major E. B. BRADLEY, Lexington.

To Fort Benjamin Harrison, Ind., from Central *Department*, *Capts*. W. T. McKINNEY, S. P. MYER, Louisville; from Walter Reed General Hospital, Capt. J. A. ROBERTSON, Fort Thomas.

To report to the commanding general, Eastern Department, *from* Albany, Lieut. L. J. GODBEY, *Berea*.

Louisiana

To Camp Cody, N. M., from Fort Bayard, Capt. W. H. SEEMAN, New Orleans. Base hospital, from Fort Bliss, Major J. W. LEA, Jackson.

To Camp Jackson, S. C., base *hospital*, *from* Camp Shelby, Lieut. S. M. BLACKSHEAR, New Orleans.

To Camp Logan, Texas, base hospital, from Camp Beauregard, Major W. E. HALL.

To Camp Sherman, Ohio, base *hospital*, from Camp Shelby, Capt. A. B. NELSON, Shreveport.

To Fort McPherson, Ga., from Boston, Lieut. R. S. KEMP, New Orleans.

To Fort Oglethorpe, base hospital, from Camp Gordon, Capt. A. L. WHITMIRE, New Orleans.

To Fort Riley, base *hospital*, from Fort Oglethorpe, Lieut. T. R. McCARLEY, New Orleans.

To Plattsburg Barracks, N. Y., from Camp Custer, Capt. T. W. EVANS, Jackson.

Maine

To Camp Bowie, Texas, base hospital, from Fort Oglethorpe, Capt. C. M. ROBINSON, Portland.

To Fort McPherson, Ga., for instruction, from Camp Jackson, Capt. D. B. CRAGIN, Waterville.

To Houston, Texas, Ellington Field, from Princeton, N. J., Capt. W. E. WHITNEY, Bangor.

Maryland

To Boston, Mass., for instruction, from Fort Oglethorpe, Lieut. G. E. LANCASTER, Bowie.

To Camp Wheeler, Ga., as camp surgeon, from Camp Meade, Major O. H. STANLEY.

To Carlisle, Pa., for instruction, from Camp Custer, Capt. W. B. PERRY, Baltimore.

To East Norfolk, Mass., from Plattsburg Barracks, Lieut. L. B. HOHMAN, Baltimore.

To Erie, Ohio, from Camp Lee; Capt. P. L. TRAVERS, Easton.

To Fort Hancock, N. J., from Camp Upton, Capt. F. K. NICHOLS, Baltimore.

To Fort McPherson, Ga., from Boston, Lieut. L. BRADY, Baltimore.

To Fort Oglethorpe, base hospital, from Camp McClellan, Capt. T. J. COONAN, Westminster; from Camp Shelby, Major A. D. ATKINSON, Baltimore.

To Newport News, Va., from Fort Oglethorpe, Capt. N. H. BRUSH, Baltimore.

To Rockefeller Institute for instruction, and on completion *to Boston, Mass.,* from Camp Meade, Lieut. T. S. MEBANE.

To Schenectady, N. Y., from Troy, N. Y., Lieut. A. L. WILKINSON, Raspeburg.

To Walter Reed General Hospital, D. C., from the Surgeon-General's Office, Capt. H. P. MAUCK, Baltimore, Lieut. C. L. BAKER, Takoma Park.

To West Baden, Ind., for instruction, from Fort Oglethorpe, Lieut. J. A. SKLADOWSKY, Baltimore.

To Williamsbridge, N. Y., from Camp Meade, Capt. G. F. SARGENT, Towson.

Massachusetts

To Arcadia, Fla., Dorr Field, from Atlanta, Lieut. A. O. McLAUGHLIN, Haverhill.

To Camp Abraham Eustis, Va., from Newport News, Lieut W. W. MARSTON, Newton.

To Camp Devens, Mass., base hospital, from Syracuse, Major C. B. STEVENS, Worcester.

To Camp Dix, N. J., from Fort Oglethorpe, Lieut. E. R. GOOKIN, Boston.

To Camp Hancock, Ga., base hospital, from Camp Sevier, Capt. E. L. HUNT, Worcester.

To Camp Kendrick, N. J., from Eastern Department, Capt. H. H. SUMNER, Lowell.

To Camp MacArthur, Texas, base hospital, from Otisville, Capt. G. L. SCHADT, Springfield. Base hospital, for instruction, from Camp Custer, Major W. E. FAULKNER, Boston.

To Camp Travis, Texas, base hospital, from San Antonio, Lieut. D. H. NISBET, Boston.

To Camp Upton, N. Y., from Eastern Department, Capt. W. H. ALLEN, Mansfield. Base hospital, for instruction, from Camp Crane, Capt. E. FLAGG, Boston.

To Carlisle, Pa., from Camp Beauregard, Major A. S. KIRKWOOD, Newton; from Fort Oglethorpe, Capts. D. L. MARTIN, Boston, W. G. CURTIS, Wollaston.

To Detroit, Mich., from Camp Meade, Lieut. H. M. BAKER, Boston.

To Fort McHenry, Md., from Camp A. A. Humphreys, Lieut. A. D. VAMVAS, Boston.

To Fort McPherson, Ga., Lieut. D. B. COLEMAN, Wellesley.

To Fort Oglethorpe, base hospital, from Camp Wadsworth, Lieut J. H. GALLAGHER, Chicopee.

To Fort Riley, base hospital, from Fort Oglethorpe, Lieut. J. J. H. HILTON, Lawrence.

To Fort Snelling, Minn., from Fort Oglethorpe, Capts. T. E. CAVANAUGH, Holyoke; C. C. BURPEE, Malden.

To Lakewod, N. J., from Fort Oglethorpe, Capt. T. W. MURPHY, Lawrence.

To Newport News, Va., from Camp Zachary Taylor, Capt. E. B. YOUNG, Boston.

To Panama Canal Department, Lieut. A. A. NAUMANN, Springfield.

To Plattsburg Barracks, N. Y., from Camp McClellan, Major G. E. McPherson, Harding.

To report to the commanding general, Northeastern Department, from Plattsburg Barracks, Lieut. J. Y. RODGER, Lowell.

To San Antonio, Texas, Kelly Field, from Ithaca, Lieut. E. E. LIGHT, East Long Meadow.

Michigan

To Alcatraz, Calif., for instruction, from Camp Kearney, Lieut. W. G. JENKINS, Newberry.

To Camp Abraham Eustis, Va., from Fort Oglethorpe, Lieut. H. S. CARR, Niles.

To Camp Custer, Mich., base hospital, Lieut. C. R. WALSH, Detroit.

To Camp Lee, Va., from Fort Oglethorpe, Lieut. J. H. HOUTON, Flint.

To Camp Sevier, S. C., base hospital, from Fort Oglethorpe, Lieut. J. H. MULLER, Grand Rapids.

To Camp Sherman, Ohio, base hospital, Capt. T. H. E. BELL, Reading; from Camp Dodge, Major W. N. SALISBURY, Ann Arbor.

To Camp Travis, Texas, base hospital, from San Antonio, Lieut. L. M. BUSH, Detroit.

To Detroit, Mich., from Camp Meade, Lieut. A. W. HEINE, Detroit.

To Fort Porter, N. Y., from Camp Custer, Capt. S. A. BUTLER, Pontiac.

To Fort Riley, base hospital, from Fort Oglethorpe, Capt. C. A. WOODRUFF, Detroit.

To Houston, Texas, Ellington Field, from Princeton, N. J., Lieut R. F. BOONSTRA, Detroit.

To Lakewood, N. J., from Fort Oglethorpe, Capt. F. B. MINER, Flint.

To Markleton, Pa., from New Haven, Capt. A. M. WEHENKEL, Detroit.

To Rockefeller Institute, for instruction in the treatment of infected wounds, and on completion *to their proper stations,* from Camp Meade, Lieut. J. K. BURNS, Jr., Detroit; from Jeffersonville, Ind., Capt. C. B. GARDNER, Alma.

The following order has been revoked: *To Sawanee, Tenn.,* from Fort Oglethorpe, Capt. C. F. SMITH, Whitehall.

Minnesota

To Camp Dodge, Iowa, from Camp Zachary Taylor, Lieut. H. OERTING, Minneapolis. Base hospital, from Camp Grant, Lieut. J. M. ARNSON, St. Paul; from Fort Douglas, Lieut. W. J. McKILLIP, Duluth.

To Camp Las Casas, P. R., from Camp Jackson, Capt. C. F. McNEVIN, St. Paul.

To Camp Pike, Ark., base hospital, from Fort Riley, Capt. L. M. BOYD, Alexandria.

To Fort Bayard, N. M., from Fort McDowell, Capt. A. PETERSON, Rochester.

To Fort Oglethorpe, base hospital, from Fort Logan H. Roots, Capt. L. A. WILLIAMS, Slayton.

To Fort Snelling, Minn., from Fort Leavenworth, Lieut. F. P. FRISCH, Kimball.

To Minneapolis, Minn., as examiner, Capt. R. S. PERRY, Minneapolis.

Missouri

To Astoria, N. Y., from Camp Custer, Lieut O. T. MOREY, Salisbury.

To Camp Crane, Pa., base hospital, from Fort Oglethorpe, Lieut. D. J. ROYER, Joplin.

To Camp Meade, Md., from Camp A. A. Humphreys Lieut. D. S. VAN HECKE, Kansas City.

To Carlisle, Pa., from Fort Oglethorpe, Capt. C. S. REHFELDT, St. Louis.

To Fort Des Moines, Iowa, from Jefferson City, Lieut.-Col. A. VON SCHRADER.

To Fort Leavenworth, Kan., from Camp Joseph E. Johnston, Lieut. E. Y. PARE, Leeton.

To Fort McPherson, Ga., from Fort Oglethorpe, Capts. W. E. MEANWELL, Columbia; R. E. NIEDRINGHAUS, St. Louis.

To Fort Oglethorpe, base hospital, from Camp Beauregard, Lieut. R. H. UNDERWOOD, Kansas City; from Camp Sevier, Lieut. H. F. PARKER, Warrensburg; from Camp Zachary Taylor, Lieut. J. C. DONOHUE, St. Louis. Evacuation hospital, from Camp Travis, Capt. J. D. PORTERFIELD, Cape Girardeau.

To Fort Riley, base hospital, from Fort Oglethorpe, Lieut. J. W. HUGHES, Leadwood.

To Fort Sam Houston, Texas, base hospital, *Capt. G. P. ALTON,* Barry.

To Kansas City, Mo., as examiner, Capt. J. G. HAYDEN, Kansas City.

To Newport News, Va., from Camp Leach, Capt. E. S. SMITH, Macon.

To Norfolk, Va., camp hospital, from Fort Oglethorpe, Lieut. W. L. MATLOCK, Sedalia.

To Rockefeller Institute for instruction in the treatment of infected wounds, and on completion *to Camp Meade, Md.,* base hospital, for instruction, from Fort Oglethorpe, Capt. V. B. KIEFFER, St. Louis.

To Washington, D. C., [illegible] *to Camp Hancock, Ga.,* from Hoboken, Capt. D. E [illegible] St. Louis.

To West Baden, Ind., [illegible] Lieut. T. E. LILLY, Kansas City.

Montana

To Camp Lee, Va., from Camp A. A. Humphreys, Capt. M. D. RIDLE, Shelby.

To Fort Oglethorpe, base hospital, from Camp Joseph E. Johnston, Lieut. E. S. PORTER, Moore.

To Fort Sill, Okla., from Norman, Okla., Lieut. *J. J.* TOBINSKI, Missoula.

Nebraska

To Camp Meade, Md., from Camp A. A. Humphreys, Lieut. R. F. DECKER, Byron.

To Carlisle, Pa., from Camp Zachary Taylor, Lieut. R. J. STEARNS, Omaha.

To Fort Jay, N. Y., from Camp Las Casas, Capt. *J. A.* STRONG, Kearney.

To Fort Oglethorpe, base hospital, from Camp Jackson, Capt. C. H. NEWELL, Omaha.

To Washington, D. C., and on completion *to Camp Gordon, Ga.,* from Hoboken, Capt. F. A. WILMOT, Bethany. On completion *to Camp Jackson, S. C.,* from Hoboken, Major E. S. TENNEY, Lincoln.

To West Baden, Ind., from Camp Dodge, Capt. A. R. DES JARDIEN, Lincoln.

The following order has been revoked: *To Camp Logan, Texas,* base hospital, Capt. C. A. ALLENBURGER, Columbus.

New Hampshire

To Boston, Mass., for instruction, from Camp Devens, Lieut. E. H. THOMPSON, Hampton.

To Camp Jackson, S. C., base hospital, from Camp McClellan, Lieut. G. S. FOSTER, Manchester.

The following order has been revoked: *To Camp Upton, N. Y., base hospital,* from Fort Oglethorpe, Lieut. F. E. SPEAR, Woodsville.

New Jersey

To Camp Dix, N. J., from Army Medical School, Lieut. J. J. MANN, Perth Amboy. Base hospital, *from* Fort Oglethorpe, Capt. G. S. WILLIS, Morristown.

To Camp Jackson, S. C., base hospital, from Camp Sevier, Capt. J. W. FARROW, Dover.

To Camp McClellan, Ala., base hospital, from Camp Jackson, Lieut. C. P. CLARK, Summit. Base hospital, for instruction, from Fort Oglethorpe, Lieut. J. J. BURNE, Newark.

To Camp Meade, Md., base hospital, from Bound Brook, N. J., Lieut. J. T. LEAHY, Bound Brook.

To Camp Meigs, D. C., as tuberculosis examiner, from Camp A. A. Humphreys, Lieut. S. R. FAIRCHILD, Penn's Grove.

To Carlisle, Pa., from Fort Oglethorpe, Capt. W. A. McMURTRIE, Morristown.

To Fort Oglethorpe, base hospital, from Camp Wadsworth, Capt. C. W. EVELETH, West Orange.

To Newport News, Va., from Camp Meade, Lieut. E. B. FUNKHOUSER, Trenton; from Washington, Capt. G. PAYNE, Cedar Grove.

The following orders have been revoked: *To Camp Sheridan, Ala.*, from Fort Oglethorpe, Lieuts. T. H. PLATT, Dunellen; J. J. LEVY, Ocean Gate. *To Camp Wheeler, Ga.*, Lieut. A. E. OLPP, West Hoboken.

New York

To Camp Abraham Eustis, Va., from Fort Oglethorpe, Lieut. G. P. MICHEL, Buffalo. Base hospital, for instruction, from Camp Meade, Lieut. H. F. VAN LOON, Albany.

To Camp Crane, Pa., base hospital, from Camp A. A. Humphreys, Capt. A. A. EPSTEIN, New York; from New Haven, Lieut. D. JUNG, Buffalo.

To Camp Devens, Mass., from Philadelphia, Lieut.-Col. I. M. UNGER, Ithaca.

To Camp Hancock, Ga., base hospital, for instruction, from Fort Oglethorpe, Lieut. M. B. SPONSLER, New York.

To Camp Jackson, S. C., from Richmond, Lieut. S. ZWERLING, Brooklyn. Base hospital, from Camp Logan, Lieut. J. M. BLANK, Brooklyn; from Camp Sevier, Lieuts. D. W. JENNINGS, Catskill; S. McLEAN, New York.

To Camp McClellan, Ala., to examine the command for nervous and mental diseases, from Plattsburg Barracks, Capt. C. A. ROSEWATER, New York.

To Camp Meade, Md., base hospital, from Fort Oglethorpe, Major P. W. NATHAN, New York; from New Haven, Major O. TEAGUE, Staten Island.

To Camp Sevier, S. C., base hospital, from Fort Oglethorpe, Lieut. J. H. BURKE, Brooklyn.

To Camp Shelby, Miss., base hospital, for instruction, from Fort Oglethorpe, Capt. J. S. DORIAN, Brooklyn.

To Camp Travis, Texas, base hospital, from Camp MacArthur, Lieut. L. A. BINGAMAN, New York.

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Surgeon E. A. SWEET, proceed to New York, for conference with the Secretary of the National Tuberculosis Association in regard to tuberculosis in the southwest.

Passed Asst. Surg. W. F. DRAPER, *proceed* to Washington, D. C., for temporary duty in connection with the Medical Reserve Corps of the Public Health Service.

Passed Asst. Surg. J. H. LINSON, *proceed* to Baltimore, Md., for conference regarding venereal disease clinics in the state of Maryland.

Passed Asst. Surg. J. G. WILSON, proceed to necessary points in the states of Ohio, Virginia, and West Virginia for inspection of nitro plants, with a view of taking them over for use as hospitals for the War Risk Insurance Bureau.

Asst. Surg. R. R. SAYERS, proceed to Joplin, Missouri, and other points in that vicinity for the purpose of establishing a tri-state sanitary district.

Asst. Surg. V. B. MURRAY, report for duty to Surgeon G. W. McCOY, San Francisco, Calif., for duty in experiments relative to the value of influenza vaccine.

Asst. Surg. H. S. MUSTARD, proceed to Wheeling, W. Va., to promulgate regulations necessary to prevent the interstate spread of influenza.

Asst. Surg. R. C. SANDIDGE, proceed to Alexandria, Va., to assume charge of Service activities at that place.

Acting Asst. Surg. B. E. ROBERTS, report to Surgeon W. H. FROST at Washington, D. C., for duty in connection with studies of the epidemiology of the recent epidemic of influenza.

Consulting Hygienists S. M. HAMILL, L. EMMETT HOLT, and J. P. SEDGEWICK, proceed to Washington, D. C., for conference in regard to questions relative to the improvement of the health of the coming generations.

Asst. San. Engr. A. J. SMALSHAF, relieved at Waco, Texas. Proceed to Columbus, Ga., for duty in extracantonment sanitation.

Asst. Educational Director W. P. GREEN, proceed to Philadelphia, Pa., to deliver a lecture before the Poor Richard Advertising Club.

Asst. Educational Director ROBERT D. LEIGH, proceed to Rochester, N. Y., to attend a meeting of the National Municipal League in regard to venereal disease control.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Personal.—Dr. Gavin J. Telfer, San Francisco, state health officer for the southern district, has been appointed to succeed Dr. Edward A. Ingram as state health officer in charge of the South Coast District. Dr. Ingram has been transferred to Sacramento.

Advice for Postinfluenza Period.—Health Officer Dr. Daniel Crosby of Oakland, in notifying the city council that it was the judgment of the health depatrment that influenza masks could be dispensed with November 20, made the following suggestions for the guidance of the people during the postepidemic period while there was a possibility of the recurrence of the disease, and while it was certain that there would still be a few cases occurring:

All persons convalescing from influenza should wear masks when going about, until three weeks after the beginning of the illness; all members of the family of the patient should wear masks for a like period. All persons finding themselves "taking cold" should wear masks while going about and while in contact with others. All employers should request, and see to it, that all employees suffering with what are commonly called "acute colds" or "fresh colds" wear masks while at work and in contact with their fellow employees or the public. The school department should cooperate in the same way with reference to both teachers and pupils. It was also suggested that persons working in neighboring cities requiring masks should continue to wear masks while in those cities.

ILLINOIS

Unlicensed Practitioner Punished.—August Labraich, Chicago, is said to have been fined $25 and costs, November 21, for practicing medicine without a license.

Sanatorium Closed.—The Weirick Sanitarium, Rockford, for the treatment of drug and liquor addicts, formerly the Broughton Sanitarium is reported to have been closed.

Proposed Union of Hospitals.—A committee of seventeen has been appointed to formulate plans for taking over the Alice Home Hospital and Lake Forest Hospital, Lake Forest, combining them into one institution.

Tuberculosis Dispensary Moves.—The free tuberculosis dispensary, for the examination and treatment of patients suffering from tuberculosis in Peoria, has been moved from 310 Chestnut Street, to 1300 Adams Street, and will be open every Saturday morning from 9 o'clock until noon.

Tuberculosis Nurses Form Union.—Thirty-four nurses enrolled in a newly formed labor union at the Municipal Tuberculosis Sanatorium, Chicago, recently. The union is affiliated with the Federation of Labor, a charter having been secured through the president of the Woman's Trade Union.

Personal.—Dr. Henry F. Hooker, Danville, has been appointed local physician and surgeon to the Illinois Traction Company, to succeed Dr. George Steely, who has resigned to enter the military service.——Dr. Arthur F. Schuettler, Chicago, was injured, November 22, in a collision between motor cars, sustaining fractures of the collar bone, nose and two ribs.

Diphtheria.—The *Bulletin* of the health department of Chicago calls attention to the considerable increase of diphtheria in October over September. In the latter month there were 423 cases and 41 deaths, or 10 per cent.; in October there were 607 cases and 98 deaths, or more than 15 per cent. In attempting to determine the responsibility for the 139 deaths from diphtheria during the two months, it was found that in about 51 per cent. of the cases the parents had not called a physician, and that in about 49 per cent. the physician had failed to make a prompt diagnosis, which delayed the administration of antitoxin.

MARYLAND

Hospital Opened.—The South Baltimore General Hospital was formally opened during the past week. Drs. Llewellys F. Barker of the Johns Hopkins University and Jane E. Nash, superintendent of the Church Home and Infirmary, made the principal addresses.

Personal.—Dr. Alexander C. Gillis, former superintendent of Sydenham Hospital, Baltimore, on duty on the Western Front, has been wounded.——Dr. Albert F. Conrey, Baltimore, formerly resident physician at Mercy Hospital, has accepted an appointment as a member of the medical staff of the leper colony at Molokai, Hawaian Islands.

Violation of Antinarcotic Law.—Dr. James A. Melvin, Baltimore, is said to have been found guilty, November 19, of violation of the Harrison Narcotic Law and to have been sentenced to imprisonment for six months. Dr. Melvin is charged with having prescribed narcotic drugs for soldiers at Fort Meade, and pleaded guilty to the charge.

Psychiatrist to Aid Police Department.—Investigation of circumstances surrounding future mysterious murders and suicides will be handled strictly on a scientific basis, according to a special order issued by Marshal Carter and transmitted to the district police captains. Dr. John Rathbone Oliver, Baltimore, who was appointed psychiatrist to the criminal courts in Baltimore several months ago, will in the future lend his scientific knowledge to the end of crime solution. He is now visiting physician at the clinic and devotes much time to work in the courts.

Making Influenza Survey.—Ten canvassers, under the direction of Capt. H. F. Smith, S. C., U. S. Army, and H. W. Streeter, sanitary engineer of the United States Public Health Service, are making a government survey in Frederick to ascertain facts concerning the spread and character of the recent influenza epidemic. The city has been marked off into districts and about 25 per cent. of the population will be reached. A house-to-house canvass is being made. This city was selected as an agricultural center, and it is understood that the rural districts of the country will be canvassed later. Maryland was selected for the survey because better records were kept here than in most states. Places have also been marked to take data in Baltimore, Cumberland, and probably Salisbury. Captain Smith has been in the service at Camp Beauregard, Louisiana, and while there studied at first hand many cases of influenza as well as the manner of its communication.

MINNESOTA

Personal.—Dr. Herbert F. Gammons, formerly superintendent of the Deer Wood, Minn., Sanatorium, has been appointed director of the publicity bureau of the Texas State Sanatorium, Carlsbad.——Dr. George S. Wattam, Warren, has been appointed temporary epidemiologist to the state board of health.

MISSOURI

Personal.—Prof. Dennis E. Jackson of Washington University, St. Louis, has been appointed professor of pharmacology in the University of Cincinnati.

Election Returns.—At the annual meeting of the St. Louis Medical Association, the following officers were elected: president, Dr. William Engelbach; vice presidents, Drs.

Rudolph S. Vitt and George F. Chopin, and secretary, Dr. Albert F. Koetter.

Influenza Dominant.—In the report of morbidity and mortality for St. Louis for the week ended November 23, of the 937 cases reported 816 were of influenza, and of the 154 deaths reported, 131 were due to that cause.

MONTANA

Personal.—Dr. Alonzo D. Eckerdt, Helena, left November 24, for a special training course at Yale University.——Dr. Phoebe A. Bottorf, Kalispell, while making a professional call and standing in the road preparing medicine for a patient, was run down by an automobile and seriously injured, the injuries necessitating the amputation of one leg above the knee.——Dr. Bennet S. Rundle, Billings, has been appointed acting assistant surgeon, U. S. P. H. S., and assigned to temporary station at Rapelje.

NEW JERSEY

Hospital for Foreign Sailors.—Word has been received from Washington that the hospital at the immigration station at Gloucester, which was opened during the epidemic period to sailors stricken with the influenza, will be continued as a hospital for foreign sailors.

Personal.—Dr. Guy Payn, medical director of the Essex County Hospital for the Insane, Overbrook, who has been called into the military service, has been granted leave of absence until December 31.——Dr. Fred A. Pringle has been appointed assistant on the medical staff of the Essex County Hospital for the Insane, Overbrook.

Tuberculosis Conference.—The Third Joint Tuberculosis conference was held at Perth Amboy, November 23. In the sociologic section employment for discharged soldiers was discussed as well as the Red Cross Christmas Roll Call, the Modern Health Crusade movement, and the effects of recent legislation on the tuberculosis cause. In the clinical section the new Army standards and the necessity for accuracy in the diagnosis of tuberculosis were discussed, and Dr. David R. Lyman, New Haven, Conn., president of the National Association for the Study and Prevention of Tuberculosis, detailed his experiences with the American Red Cross in France.

NEW YORK

Justices Must Report Prostitution Convictions.—The attorney general of the state has recently sent a letter to all justices of the peace of the state, calling their attention to the amendment of the Public Health Law, made by the legislature of 1918, by which it becomes obligatory for such justices to report to the local board of health all persons convicted under the various laws relating to prostitutes and prostitution, in order that the board of health may determine the presence or absence of venereal disease in such persons.

Typhoid at Herkimer.—One hundred and five cases of typhoid fever were reported from the village of Herkimer during October. This outbreak occurred conjointly with the influnza epidemic, and since, notwithstanding a provision of the state sanitary code requiring Widal tests in all cases suspected of being typhoid, a number of physicians failed to confirm their diagnosis by agglutination tests, there is a possibility that a few of these cases may have been influenza. The outbreak was clearly the result of the use of polluted water. For several days during September polluted water was pumped into the mains from West Canada Creek, and from the hydraulic canal while the chlorinating apparatus was not in operation. The municipal water commission of Herkimer had been previously warned of the danger of permitting the use of raw water from this source. Twenty-five additional cases had been reported up to November 23, but most of these were in all probability secondary to previously existing cases.

New York City

Personal.—Dr. Anthony Bassler has been appointed professor of gastro-enterology at Fordham University.——Dr. Henry E. Pflug, Brooklyn, and Dr. Charles F. W. Horn have been appointed temporary police surgeons.

Sentenced for Illegal Practice.—Henry Miller, Brownsville, Brooklyn, charged with the illegal practice of medicine, is said to have been found guilty and to have been sentenced, November 19, to imprisonment for four months in the Kings County jail.

Safety Institute Changes Name.—The supreme court has granted permission to the American Museum of Safety to change its name to the Safety Institute of America. The institute has plans for the extension of its activities during the coming year.

Anniversary Address.—The anniversary address of the New York Academy of Medicine was delivered, December 5, by Edwin G. Conklin, professor of biology in Princeton University, on "The Biology of Democracy with Especial Reference to the Present World Crisis."

Medical Society of the County of New York Elects.—At its one hundred and thirteenth annual meeting, held November 25, the Medical Society of the County of New York elected the following officers for the ensuing year: president, Col. Charles Howard Peck, M. C., U. S. Army; first vice president, Dr. Charles H. Chetwood; second vice president, Dr. George Gray Ward, Jr.; secretary, Dr. Daniel S. Dougherty; assistant secretary, Dr. J. Milton Mabbott; treasurer, Dr. James Petersen, and censors, Dr. William S. Gottheil, Dr. Gustav G. Fisch and Dr. Herbert B. Wilcox.

Debarkation Hospital Opens.—Army Hospital No. 3, at Eighteenth Street and Sixth Avenue, formerly the Greenhut Building, was opened, November 23, to receive its first consignment of wounded and convalescent soldiers. On that day 426 American soldiers and twenty-four officers were transferred from an incoming transport to the hospital, from which they will be distributed to other hospitals and institutions for convalescent soldiers. The hospital is headed by Major William J. Monaghan of the Medical Corps and is prepared to care for from 3,000 to 4,000 men.

PENNSYLVANIA

Personal.—Dr. Evan O'Neill Kane, Kane, who has been seriously ill as the result of roentgen-ray burns, is reported to be out of danger.——Dr. Edward H. Gingrich, city health officer of Lebanon, who has been seriously ill, is reported to be improved.

Appreciation of Volunteer Workers.—Dr. B. Franklin Royer, Harrisburg, acting commissioner of health, has sent a note of appreciation to the thousands of volunteers, doctors, nurses, and others who so loyally and unselfishly assisted in the care of the sick during the recent epidemic of influenza in the state.

Society Anniversary.—The fortieth anniversary of the founding of the Lackawanna County Medical Society was celebrated, November 19, in the rooms of the society at Scranton. Addresses were delivered by the only two surviving charter members of the society, Dr. Louis H. Gibbs, West Scranton, who spoke on "Organization," and Dr. Sumner D. Davis, Jermyn, who delivered an address on "Disadvantages of the Physician in Olden Times."

Memorial Building for Hospital.—Pierre S. Dupont has presented $300,000 to the West Chester Hospital for the erection of a building in "memoriam" of Lewis Mason, who was Mr. Dupont's chauffeur, and who died of influenza during the epidemic. The money has been made immediately available and plans for the new building are being prepared. The old main building is to be torn down and will be replaced by a steel and concrete building. The wings on either side of the present building—both memorials—will be retained.

Officers for Orphan Committee.—Dr. B. Franklin Royer, acting commissioner of health, has appointed Dr. Nathan C. Schaffer, Harrisburg, superintendent of public instruction, as chairman, and Dr. Samuel McClintock Hamill, Philadelphia, chief of the division of child hygiene, secretary of the committee appointed to collect information as to the commonwealth surrounding the number of children who were rendered orphans because of the recent epidemic of influenza in the state. Dr. Wilmer R. Batt, Harrisburg, state registrar of vital statistics, was appointed statistician of the committee.

Philadelphia

Cost of Epidemic.—At the next session of city councils a request will be made by Director William Krusen for a special appropriation to meet the expense incurred by the municipality in fighting the recent influenza epidemic and the actual expense for service and materials furnished will amount to about $75,000.——According to the report of the health department for the week ending November 30, influenza caused twenty-six deaths, sixteen of which were of adults, and pneumonia caused thirty-one deaths, of which twenty-seven were of adults.

Personal.—Dr. Astley P. C. Ashhurst, who went to France as a major in command of Base Hospital No. 34, unit of the

Episcopal Hospital, has been promoted to the rank of lieutenant-colonel and placed in charge of all the hospitals in the Mantes Sector. His place as director of Base Hospital No. 34 has been taken by Dr. Emory G. Alexander.——Dr. Hyman I. Schenker has been made assistant school medical inspector, and Dr. Edward Haentze has been appointed outdoor physician, bureau of health and charities.——Dr. John Leo Donahue, who has been serving with the British Army, has been commissioned captain in the American Army.

Influenza Conference.—A conference on the influenza epidemic, attended by medical men from the South, middle Atlantic states and New England states, was held at the hygiene laboratory, at the University of Pennsylvania, November 29 and 30. Dr. Wilmer Krusen, director of public health and charities, presided at the sessions. According to Dr. Krusen, figures obtained in Philadelphia showed little difference in the death ratio between whites and negroes, and the density of population appeared to have no effect on the spread of the epidemic as there were 118 deaths in the thickly settled third ward while there were 295 deaths in the twenty-second ward. Among the speakers were: Dr. Edwin W. Kopf, New York, chairman of the vital statistics of the American Health Association; Prof. R. E. Chaddock and Prof. C. C. Grove of Columbia University, Dr. William H. Guilfoy of the Department of Health in New York City and Dr. Frederick L. Hoffman, Newark, N. J., of the Provident Life Insurance Company. This conference was preparatory to the American Public Health Association's convention in Chicago, to be held the second week in December.

SOUTH CAROLINA

Action Taken on Noncompliance with Epidemic Closing Regulations.—In resolutions passed unanimously by the city board of health of Charleston, November 20, the action of the authorities of the Cathedral of St. John the Baptist in holding services, November 3, during the epidemic of influenza, in contravention of the regulations adopted by the health authorities with the approval of the local medical society and others of the local profession, was severely censured, in lieu of more drastic action that might have been taken under the powers of the board. This was the only notable instance in which the quarantine measures of the health authorities were violated during the epidemic, cooperation with the health board being otherwise commendably carried out. In a similar violation of the regulations of the city and health authorities in Los Angeles by members of the Christian science church the supreme court of the state upheld the validity of the ordinance requiring closing, and denied writs of habeas corpus in the cases of five men arrested for its violation by holding a meeting in the church during the epidemic.

TEXAS

State Board Meeting.—The Texas State Board of Medical Examiners held its semiannual meeting in Dallas, November 19 to 21. The eleven members of the board representing the entire state and the various physicians of medicine and osteopathy examined about thirty applicants.

Personal.—Dr. William A. Davis, state registrar of vital statistics, Austin, and secretary of the state board of health for the last five years, has received an offer from the state of Georgia for a similar position at an increased salary. ——Dr. Guy H. Reed, Beaumont, has been appointed a member of the state board of health, to succeed Dr. Louis M. Weinfield, San Antonio, who has resigned.

WISCONSIN

Hospital Opened.—The South Side Hospital, Oshkosh, has recently been opened under the charge of Dr. John E. Schein.

Sanatorium for Grant County.—At the meeting of the county board of Grant County held at Lancaster, it voted unanimously for the construction of a tuberculosis sanatorium.

Personal.—Dr. James P. Lenfestey, DePere, has been elected county physician of Brown County, to succeed Dr. Frank L. Crikelair, Green Bay, who is going overseas.——Dr. John R. Hughes, Dodgeville, has been appointed local surgeon for the Chicago and Northwestern System, to succeed Dr. Walter S. Lincoln, deceased.——Seth M. B. Smith, Wausau, has returned to America, after serving as director of a hospital for refugees at St. Etienne, France.

CANADA

Hospital News.—Major Thomas D. Archibald, Toronto, has been placed in command of the Rosedale Military Hospital, Toronto. It has a capacity for 2,000 soldiers. Major Archibald was transferred from Whitby, Ont., where he held a similar position.——The Guelph Ontario Military Hospital will probably be changed into a hospital for convalescent soldiers with tuberculosis. The first lot of tuberculous soldiers has arrived, seventeen having been transferred from Gravenhurst. The present medical staff will remain in charge of the institution.——A consolidated military hospital scheme is proposed for Victoria, B. C. The city has offered the site for the central institution, the loan to extend for two years after the termination of the war.——The Jordan Memorial Hospital, New Brunswick, has passed into the hands of the Invalided Soldiers' Commission of Canada. The federal authorities have taken a five-year lease of the institution; and civil patients will be cared for at a rate of $15 per week. This hospital was presented to the province originally by Mrs. J. Clarke Jordan, and she is quite willing the soldiers should have the institution.——The Balfour Sanitarium for the Treatment of Pulmonary Tuberculosis, British Columbia, has been changed from a military to a civilian hospital. At the present time Captain Olson is on indefinite leave of absence from the C. A. M. C. and is acting as medical superintendent in charge.

Public Health Notes.—Col. John W. S. McCullough, Toronto, provincial health officer for Ontario, states that placarding and quarantine is not required in Ontario for influenza. While such laws are in force in certain states of the American Union and also in some provinces of Canada, the majority —four-fifths of medical officers of health in the two countries —give it as their opinion that any such laws are incapable of enforcement. At the outset of war the Dominion government was without facilities for a supply of typhoid vaccine and the Ontario Board of Health alone of all the provinces had such facilities. That board has supplied gratuitously to the Department of Militia and Defense about $250,000 worth of typhoid and paratyphoid vaccine, which has proved an invaluable aid for the prevention of those diseases among soldiers.——A central board of health is now being advocated by the medical fraternity for the border cities of Ontario; and an active movement is on foot to bring about amalgamation of the different boards of health of the cities concerned. One central office and one central medical officer of health would enable the Ontario Department of Health to be more efficiently managed.——The medical profession of Halifax, N. S., answered the urgent call of the state of Massachusetts for assistance to fight the spread of influenza, and a detachment of nurses and doctors was sent which was immediately acknowledged by Governor McCall.

GENERAL

Improving City Milk Supplies.—During the last year the Dairy Division of the United States Department of Agriculture, through its specialists, has given assistance to thirty-six cities in fourteen states in the sanitary production and handling of milk. In addition, assistance was given by the United States Public Health Service in the way of sanitary milk surveys, etc., in fifteen extracantonment zones. In the assistance rendered by the government to local communities all phases of city milk supply are covered, such as inspection of dairies, milk plants and other distributing centers, analysis, chemically and bacteriologically, of milk samples, and, when necessary, help in the installation of laboratories and technic and in the interpretation of the results of chemical and bacterial analyses. Advice is also offered in framing ordinances to cover dairy and milk conditions, and milk contests are encouraged for the purpose of creating rivalry among dairymen, which tends to improve the milk supply. In these contests experts from the department act as judges in scoring the product.

Influenza.—In general, influenza continues to abate throughout the country, though there are some cities and some sections in which there is a recrudescence or an accession of the disease. Kansas is one state in which the disease appeared to be increasing the latter part of November, as indicated by reports from Concordia, Leavenworth and Topeka. At Butte, Mont., there seemed to be an exacerbation, and physicians were rebuked for not promptly reporting new cases. November 25, the Public Health Service was asked to send physicians and nurses to the coke district in Fayette County, Pa., on account of the disease. At Scranton, Pa., up to November 22, there had been 5,992 cases with 778 deaths. The disease was abating rapidly. In New York state on about the same date the disease had practically subsided. A number of municipalities in the western part of the state, where outbreaks had been more recent, reported temporary increases in the number of cases following the peace celebrations. Up to that time 257,758 cases had been reported in the state outside of New York City. In *Public Health Reports,* November 22, appears a continuation of the tabulated record of cases throughout the country, as reported to the U. S. Public Health Service, together with an account of influenza among the soldiers abroad, covering the time up to October 21.

Orthopedic Journal Expands.—It is announced that the *American Journal of Orthopedic Surgery,* the official publication of the American Orthopedic Association, which has been the only journal in the English language devoted to orthopedic surgery, will now extend its field of activity and will become also the organ of the newly-formed British Orthopedic Association under the name of the *Journal of Orthopedic Surgery.* This has been brought about through the increased interest and importance of the subject of orthopedics on account of the war. It is believed the purposes of the orthopedic branch of surgery will be best served by the amalgamation, an idea long cherished by Lieut.-Col. Robert B. Osgood, M. C., U. S. Army, Boston, who promoted the establishment of the American journal. The journal will be published from the present offices in Boston under the management of Ernest Gregory. The committees appointed by the British Orthopedic Association consist of R. C. Elmslie, M.S., F.R.C.S., editor, London; T. R. Armour, F.R.C.S.; W. H. Trethowan, F.R.C.S., and H. Platt, M.S., F.R.C.S.; while Charles F. Painter, M.D., Boston, and Robert W. Lovett, M.C., Boston, comprise the committee appointed by the American Orthopedic Association. Miss Hannah Lissner, Boston, has been appointed in charge of the editorial department of the journal in America.

FOREIGN

Deaths Abroad.—Dr. **Joseph Kidd,** London; M. R. C. S., England, 1846, M. D. U. K. C. Aberdeen, 1853; aged 94; one of the most notable homeopathic practitioners of England, and physician to Lord Beaconsfield; died at his home, in Blackheath Park, recently.——**Jose Palomeque,** one of the leading Mexican physicians established in Havana, Cuba, a graduate of the University of Paris; a practitioner for more than fifty years; died in Lenox Hill Hospital, in New York City, October 30.

CORRECTION

Method for Staining the Diphtheria Bacillus.—We are informed by Capt. F. A. Beck that in his article published July 13 with this title, the following change should be made: Bismarck brown 0.480 mg. should be 0.480 gm. In the article published Nov. 16, 1918, under the title "Method for Preparing the Eosinate of Methylene Blue and Method for Staining" eosin yellowish (water-soluble) 0.470 mg. should be 0.470 gm. and methylene blue 0.400 mg. should be 0.400 gm.

SOUTH AND CENTRAL AMERICA, MEXICO AND WEST INDIES

Cuban Donations for the War Victims.—The *Cronica Medico-Quirurgica* of Havana states that the official committee appointed by the government to distribute the funds voted in aid of the victims of the war, has sent $125,000 to France; $80,000 to Belgium; $100,000 to Italy, and $100,000 to England. These sums are the state donations and do not include the gifts by private individuals. The Cuban Red Cross has received half a million which it has devoted to the same purposes.

The Motile Bacillus of Influenza.—At the meeting of the Academia de Ciencias of Havana, November 22, Dr. L. Plasencia, a leading microscopist, presented evidence that a coccobacillus isolated by him constantly from the sputum in cases of true *influenza* bears a causal relation to the disease. It was not found in other diseases, and it reproduced in monkeys a disease closely similar to influenza in the human. The coccobacillus in question is a little broader than the Pfeiffer bacillus, its *minimal* length about 0.6 micron, its extreme length (only in cultures) 2.1 micron, the average about 0.9. In width it varies from 0.1 to 0.3 micron. The grouping is characteristic as each bacillus is separate, even when in clusters. It takes the anilin stains but requires a little longer contact than other bacilli. The most characteristic feature is its motility, equal to that of certain strains of paratyphoid bacilli. As he knows of no previous description of this bacillus, he has named it the *Bacillus influenzae motilis.*

CUBA LETTER

Havana, Nov. 20, 1918.

The Epidemic of Influenza

There are at present about 12,000 cases of influenza in Cuba; but the epidemic is relatively mild, as the cases of bronchopneumonia represent only 3 per cent. of the total, and the statistics show the death rate to be slightly above 1 per cent. The communities in which the disease is most prevalent are Camaguey, with 4,000 cases, and Santiago de Cuba, with 3,000.

The Sociedad de Estudios Clinicos of Havana dedicated an extraordinary meeting to the study and discussion of the epidemic; Dr. L. Ortega, who was appointed speaker, condemned the use of vaccines as a routine measure and said that he saw no scientific basis for the widespread use of antidiphtheric serum against pneumonia and bronchopneumonia. There is no specific treatment for the disease that we call influenza, and until the discovery of the germ puts us on the road to the truth, we can do no more than undertake symptomatic treatment.

DR. PLASENCIA'S RESEARCH WORK

Dr. L. Plasencia, professor of microscopy of the University of Havana, has discovered in the sputum and in the throat of individuals attacked with the present epidemic disease a new micro-organism which at first they thought to be Pfeiffer's but which later they found to be motile, to grow in ordinary mediums as well as in blood agar, and to produce in monkeys a typical attack of the disease: sudden high temperature, catarrhal symptoms and great prostration. The curve of the temperature takes exactly the same course as in human cases. Dr. Plasencia asserts that he has found this germ, which he believes to be specific of the disease, in 90 per cent. of the cases he has examined. Dr. Plasencia is a well known and reliable man, and is not a vaccine manufacturer.

National Federation of Physicians

At the last regular meeting of the Sociedad de Estudios Clinicos, Dr. A. Salcines delivered an address proposing the union of all the physicians of Cuba in a national federation. According to Dr. Salcines' proposition, every physician should belong to the federation and should not be allowed to practice without his membership certificate. In this manner all quacks and unregistered physicians would be put out of business, as well as those graduated physicians who do not carry their practice under strictly ethical conditions. The society took under consideration Dr. Salcines' idea and appointed a commission to study the foreign as well as the home legislation on the matter.

Death of Dr. J. A. Clark

Dr. J. A. Clark, former director of the municipal medical service of Havana, died at his home, November 18, from cerebral hemorrhage. Dr. Clark was at the time of his death director of charities of the republic.

PARIS LETTER

Paris, Nov. 7, 1918.

International Scientific Relations After the War

The Académie de Médecine appointed a special committee to consider this question. The commission consisted of Professors Laveran, Albert Robin, Achard and Drs. Regnard and Siredey. October 15, the Academy, believing personal relations between scientific men of the two groups of belligerents to be impossible until reparation and expiation of the crimes which have put the Central Empires under the ban of humanity permit them again to enter the concert of civilized nations, adopted the following resolutions submitted by the committee:

1. The Central Empires shall be compelled by a provision of the treaty of peace to retire from international scientific associations established by diplomatic conventions and implying personal relations between the members. This exclusion would not apply to common action solely concerning administrative relations indispensable between such public services as those affecting the regulation of navigation, railways, telegraphs, etc.

2. As soon as circumstances allow, those international conventions not belonging to the two categories noted above shall be dissolved by each of the competent groups of the Entente and of the United States of America in accordance with the statutes and regulations of each of them. New associations recognized to be needed for the progress of the

sciences and their application shall be established forthwith by the Allies and the United States, with the eventual cooperation of neutrals.

3. The governments of the allied countries and of the United States shall refrain from sending delegates to any international assembly at which representatives of the Central Empires would be expected to figure. It is desirable that the citizens of the Entente countries and of the United States should adopt the same line of conduct and not take part in any enterprise in which the citizens of the Empires would collaborate.

4. Inquiry should be made as to the steps to be taken to establish intimate collaboration between the Allies and the United States, particularly in the domain of allied science and in the publication of certain bibliographic works.

Anti-Influenza Measures in Schools

The prefect of the Seine district has instructed the mayors, medical inspectors and principals of the schools of Paris and of the département de la Seine to take the following measures with regard to the present epidemic of influenza: (1) Stop all meetings in school buildings; (2) inquire as to the reason for absence of any pupil, and inform, without delay, the bureau of medical inspection of schools of the results of such inquiry; exclude every child from the school who presents any symptoms of indisposition, and have him taken home, notifying the family to secure medical attendance for the child at once; (3) advise families to keep their children at home if they do not feel well; (4) exclude from school the brothers and sisters of the patient. The principal of the school should inform the principals of the schools attended by the brothers and sisters of their own pupils suspected of having influenza; (5) clean the floors and blackboards and desks often with Javelle water, creolin or a 20 per cent. aqueous solution of liquor formaldehyd; (6) do not close down the whole school, but dismiss for fifteen days all classes three fourths of whose membership is absent because of influenza; the school medical inspector may, however, close the school if the situation is grave; (7) proper antisepsis of the nasal fossae.

The Germans and the Pasteur Institute of Lille

The *Figaro* recently published a letter written by Dr. Calmette, October 15, and addressed to the mayor of Lille. Dr. Calmette, who had remained at the head of the Lille Institut Pasteur ever since the German invasion, in this letter protested against the Germans taking away the last three horses which had been used for the production of antidiphtheritic serum. A veterinary had pronounced these horses as being unfit for any service; they were not even shod, and they were absolutely needed by the institute for the production of diphtheria antitoxin. His protest was ineffective, although this action was a violation of the Hague peace conventions, an infringement of the rights of men, and an act of gross inhumanity because it deprived the already sorely tried and unfortunate civil population of the much needed serum for the treatment of diphtheria, especially at a time of the year when this disease is of common occurrence among children. Calmette says that at the proper time he will bring this matter to the attention of all learned societies the world over. Calmette's wife was taken to Germany last year as a hostage.

The Bread Ration of Young Soldiers

During the duration of the influenza epidemic, the soldiers of the class of 1919 who are still in the garrisons will be allowed a bread ration of 700 to 800 gm.

Helping to Fight Influenza

The under-secretary of state of the Service du Santé militaire has placed the mobilized physicians at the disposition of the civil population whenever there is an insufficient number of physicians in any given vicinity. The medical members of the class of 1888 (50 years of age) and older ones, can be sent to points where medical aid is demanded by the needs of the moment. The under-secretary has also asked convalescing physicians to help out, if their state of health permits, and render such service as they can wherever they may happen to be stationed.

Leading Citizens of Lille Protest Against German Atrocities

At the meeting of the Académie de médecine held October 29, the secretary read a letter signed by Dr. Calmette, director of the Institut Pasteur at Lille, M. Parenty, director of the tobacco manufacturers of Lille, and M. Witz, professor on the science faculty of Lille, in which these savants protest against the infamous treatment imposed on the people of Lille by the German authorities. The Academy declared itself as being in sympathy with the writers of the letter, and voted a resolution to the effect that henceforth it would not collaborate with any German publication, nor participate in any scientific meetings or any international congress with German colleagues who have not previously publicly stated their disapprobation of these outrages committed by their government during the war. This letter was also read before the Académie des Sciences at its meeting held October 30.

School for the Blinded at Lille

The war fund for blinded soldiers and sailors founded by Mr. and Mrs. George A. Kessler of New York will supply the money needed to open an institute at Lille for the blinded soldiers of northern France who wish to return near their homes in the territory recently evacuated by the enemy. This decision was taken on request of the French government. More than 200 blinded French soldiers who came from the northern provinces are now resident in the numerous asylums distributed throughout France.

Deaths

Dr. Viault, professor of general anatomy and histology in the Bordeaux medical faculty is dead; likewise, Dr. Albert Auvray, formerly director of the school of medicine and pharmacy at Caen.

Professor Paul Dubois of the University of Berne, author of many publications on diseases of the nervous system, died recently at Berne, aged 70.

Personal

At its last meeting, the Académie des Sciences unanimously elected Marshall Foch *académicien libre* to succeed the late professor Léon Labbé.

LONDON LETTER

London, Nov. 5, 1918.

The National Physique

In the *Observer*, Prof. Arthur Keith discusses the question of the national physique. He refers to the declaration of the prime minister, Mr. Lloyd George, who asked the minister of national service, "How many more men could we have put into the fighting line if the health of the country had been properly looked after?" and was told, "At least one million." In the course of voluntary work at the ministry of national service, Prof. Keith obtained the results of the surveys that are being carried out all over the country by the medical boards in the examination of recruits, and finds that the prime minister has understated the seriousness of the position. Dividing the population into four grades, he considers that if 1,000 young men be taken at random and graded according to their physical fitness, the following should be expected under good conditions: Grade 1, 700; Grade 2, 200; Grade 3, 75; Grade 4, 25. Grade 1 includes men fit for general military service, and Grade 4 men unfit for any of the duties of a soldier. Grade 2 and 3 are intermediate. The actual figures obtained from a large industrial town were: Grade 1, 190; Grade 2, 270; Grade 3, 410; Grade 4, 430. The objection, however, may be raised that the present population of our towns is merely a residue left after the departure of the fit young men to active service in the earlier years of the war. After the age of 30, men tend to become degraded, that is, to pass down the grades. On turning to trades that have been exempted from military service in the earlier years of the war, the objection just made is largely removed; but the figures remain very serious. They are: Grade 1, 270; Grade 2, 152; Grade 3, 158; Grade 4, 420. Professor Keith attributes these results to slum life. Slums produce children who become men of Grades 3 and 4. Another factor is wage earning by women, who are unable to look after their children.

The Question of the Unfit

At a meeting of the National Birth-Rate Commission, Major Leonard Darwin, son of Charles Darwin, said he was inclined to think that we should be driven to some form of sterilization as the only way to deal with the question of the unfit, but that we shall require to know a great deal more before we can move along that path. We shall want to be quite sure that sterilization does not affect the character of the person sterilized, and that if it proves a failure it does not affect the health of any child that may be born. Turning to the question of the racial effects of public expenditure intended to lessen the strain on family life, the effects to be considered are (1) the mother and the children, and (2) the future output of children. With regard to the immediate results on the family, a complex balancing of good and evil effects has to be considered. Improvements in environment cannot be relied on to promote racial progress. It is when looking to the generations of the future that questions of heredity are seen to be of great importance. Good homes contain persons on the average somewhat innately superior to the inhabitants of bad homes, and to decrease the birth rate in bad homes would make for social progress. Social reformers ought to desire to lessen the output of children from bad homes without any reference to the effects of natural inheritance. On this account, it seems that expenditure likely to increase fertility should not be made applicable to bad homes. But expenditure intended to improve hygienic conditions often also tends to promote fertility. In considering the effects of such expenditure, the malthusian arguments must not be overlooked. But help will doubtless be demanded by many reformers to better the conditions in the worst homes. All such help, whether given without breaking up the home or in institutions, is likely to increase fertility. We are, therefore, on the horns of a dilemma. We must either refuse to give assistance to those continuing to live degraded lives, or we must promote enduring racial harm. As the result of a choice between these two evils, no help should be given to homes below a certain standard of decency, suitable institutional assistance being always available for their inhabitants. Harm as well as good will always result from public assistance to selected individuals. This argument points to help being given universally and without selection. But such help would do racial and other harm, because of the heavy taxation thus necessitated and for other reasons. This system of relief should be adopted only when the benefits aimed at are otherwise unattainable. Free feeding and doles to families should be given only in genuine cases of urgent need.

Venereal Disease and Man Power

In a previous letter, the objections that have been made to the defense of the realm regulation, known as 40 D, which makes it penal for any woman having venereal disease to have intercourse with or solicit intercourse with a British soldier, were discussed. The regulation was founded on information that the spread of venereal disease in the British and colonial forces involved a serious loss of man power. Up to the end of August, seventy-eight persons have been convicted of breaches of the regulation, of whom thirty-seven pleaded guilty. The removal for a time of these centers of infection, and the deterrent effect of the regulation on others, have already resulted in a diminution of venereal disease in some army districts. The United States authorities have asked that the regulation be extended so as to apply to their troops in this country, and the governments of Canada and New Zealand have made similar regulations for the protection of their troops in the dominions. In these circumstances the government has decided that the regulation must for the present be retained. It has, however, appointed a small committee to consider what modifications, if any, should be made in its terms or in the procedure for enforcing it. The committee includes Sir Malcolm Morris, a medical woman, and a number of well known philanthropic workers.

Marriages

Asst. Surg. Hardy Vernon Hughens, *Lieutenant*, U. S. Navy, on duty at Great Lakes, Ill., to Miss Agatha Alethea Roemer of Waukegan, Ill., November 28.

Capt. George Flanders Wilson, M. C., U. S. Army (retired), Portland, Ore., to Mrs. Bessie M. Marshall, also of Portland, November 26.

Lieut. Charles Preston Mangum, M. C., U. S. Army, Kinston, N. C., to Miss Margaret Edwards of Chicago, November 6.

Lieut. Harold Thomas Hyman, M. C., U. S. Army, to Miss Rita Abrahams, both of New York City, November 21.

Joseph Luke DeCourcy, Cincinnati, to Miss Frances Cornelia Bickett of Chicago, November 28.

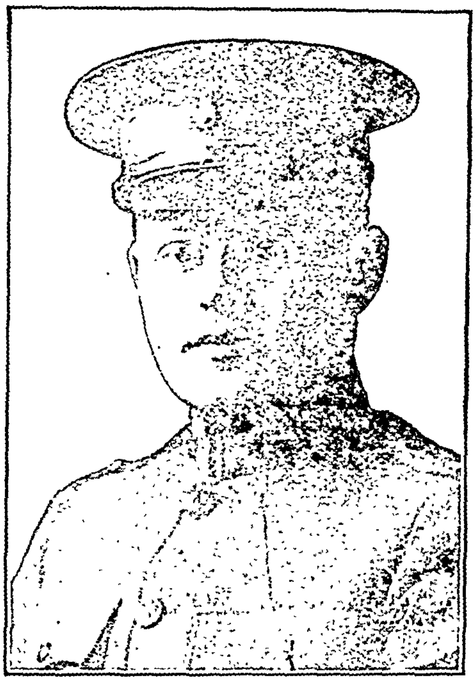
Harold Hill Walker, Kansas City, Mo., to Miss Wanda Ramsey of Omaha, November 10.

Adolph Steiner, Lima, Ohio, to Miss Gertrude Becker of Chicago, recently.

Deaths

Lieut. August Adrian Strasser ⊕ **M. C., U. S. Army**, Arlington, N. J.; College of Physicians and Surgeons in the City of New York, 1896; aged 44; a member of the American Association of Obstetricians and Gynecologists and New York Academy of Medicine; and once president of the New Jersey Academy of Medicine; chief of the children's disease clinic, in the German Hospital, Newark; a member of the staff of the Womens and St. Michaels hospitals, Newark; who entered the Medical Reserve Corps, June 1, 1917, and was on duty at Fort Oglethorpe, Ga., where he received an honorable discharge; died at Newark, N. J., November 20, from cerebral hemorrhage.

Capt. Theodore Fletcher Mead ⊕ **M. C., U. S. Army**, New York City; Cornell University Medical College, New York City, 1912; aged 33; who was appointed assistant visiting physician at Bellevue Hospital in January, 1917; entered the United States service in June, 1917, and sailed for France, June, 1918, and was on duty with the One Hundred and Fourth Field Artillery; died, October 30, from wounds received in action.



Died in the Service
in France
Capt. Theodore F. Meade, M. C.,
U. S. Army, 1885-1918

Capt. Frank Henry Knight ⊕ **M. C., U. S. Army**, Brooklyn; College of Physicians and Surgeons in the City of New York, 1899; aged 42; a specialist in gynecology; formerly visiting surgeon at St. John's and the Kings County hospitals, and the Episcopal Orphan Asylum and Home for the Aged; visiting gynecologist to the Swedish and Methodist Episcopal hospitals; on duty with Base Hospital No. 23 at Portsmouth, England; died from pneumonia, October 28.

Capt. Halstead Robert Wright ⊕ **M. C., U. S. Army**, Columbus, O.; Ohio State University, Columbus, 1910; aged 43; a member of the American Academy of Ophthalmology and Oto-Laryngology; a specialist in diseases of the eye; formerly instructor in physiology and pathology of the eye in his alma mater; on duty at Base Hospital No. 14, Fort Oglethorpe, Ga., died at that place, October 17, from pneumonia following influenza.

Major Shadworth Oldham Beasley ⊕ **M. C., U. S. Army**, San Francisco; Cooper Medical College, San Francisco, 1897; aged 42; assistant clinical professor of obstetrics and gynecology in Leland Stanford Junior University; major of volunteers during the war with Spain with service in the Philippine Islands; on duty with the American Expeditionary Forces in France; is reported to have been killed October 14.

Charles Emery Payne, Brooklyn, N. Y.; New York Homeopathic Medical College, 1903; aged 36; consulting laryngologist and rhinologist to the Jamaica and Cumberland Street hospitals, and attending physician to the home for Consumptives; laryngologist, rhinologist, and assistant oculist and aurist to the Brooklyn Nursery and Infants' Hospital; died at his home, November 18, from pneumonia.

Robert Goodwin Marriner, Menominee, Mich.; Northwestern Medical School, Chicago, 1881; aged 61; a member of the Michigan State Medical Society; attending physician and surgeon to St. Joseph's Hospital, Menominee; city health officer; who fell from a porch while making a professional call, November 12, fracturing two ribs, died at his home, November 21, from secondary pneumonia.

Jacob Rosenberg, New York City; University and Bellevue Hospital Medical College, New York City, 1914; aged 29; a member of the Medical Society of the State of New York; surgeon to Mount Sinai, Hudson Street, and Gouverneur hospitals; died at his home, November 14, from pneumonia following influenza.

William N. Yates ⊕ Fayetteville, Ark.; Missouri Medical College, St. Louis, 1878; aged 67; health officer of Fayetteville, and a member of the Washington County Board of Health; for many years a member of the board of trustees of the University of Arkansas; died at his home, November 17, from pneumonia.

Lieut. Samuel Lewis ⊕ **M. C., U. S. Army,** Brooklyn, N. Y.; Long Island College Hospital, Brooklyn, 1917; aged 22; on duty with the Fifty-Second Field Ambulance, British Expeditionary Forces in France, is reported to have been killed in action on the Somme, August 28.

John Solomon Meltzer, New York City; University and Bellevue Hospital Medical College, 1912; aged 29; a member of the Association of American Physicians; visiting physician at Mount Sinai and Lying-In Hospitals, New York City; died at his home, November 16.

Capt. George Edward Farr ⊕ **M. C., U. S. Army,** Shelbyville, Mo.; University Medical College of Kansas City, Mo., 1906; aged 39; on duty on the Mexican border; died in the base hospital, Brownsville, Texas, October 30, from pneumonia following influenza.

James Corbett Rathbun, Danville, Ill.; Bennett Medical College, 1909; aged 37; a member of the Illinois State Medical Society; while driving across the interurban tracks in Danville, November 13, was struck by an interurban car and instantly killed.

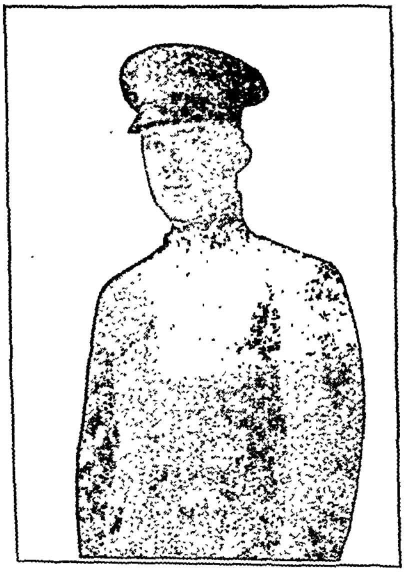
Thomas William Hovorka, St. Cloud, Minn.; Minneapolis College of Physicians and Surgeons, 1902; aged 44; a member of the Minnesota State Medical Association; died at his home, October 17, from pneumonia following influenza.

William B. Melick, Fort Edward, N. Y.; Albany, N. Y., Medical College, 1884; aged 60; a member of the Medical Society of the State of New York; at one time coroner of Washington County; died in New York City, November 3.

Lieut. Arthur Francis McQuaid ⊕ **M. C., U. S. Army,** Chicago; Loyola University, Chicago, 1915; aged 28; on duty at British war hospitals in England from October, 1917, to July, 1918, and since that time serving with the British Expeditionary Forces in Flanders and France; is reported to have been killed in action, October 15.

Glenn Charles Spurgeon ⊕ Seattle; Northwestern University Medical School, Chicago, 1904; aged 44; a member of the staff of the Eye, Ear, Nose and Throat Infirmary, Seattle; died at his home, October 29, from pneumonia following influenza.

Herman Oechsner ⊕ New Orleans; Tulane University, New Orleans, 1899; aged 56; also a graduate in pharmacy; a member of the state board of health in 1908; died at his home, September 30, from intestinal toxemia.



Died in the Service
in France
Lieut. Arthur F. McQuaid, M. C.,
U. S. Army, 1890-1918

Lieut. Harry Shafer Marcley ⊕ **M. C., U. S. Army,** New York City; University of Syracuse, N. Y., 1911; aged 32; anesthetist to the Hospital for Ruptured and Crippled, New York City; on duty at Camp Eustis, Va.; died at that place, November 18.

John Calvin McClurkin, Chicago; Bellevue Hospital Medical College, 1871; aged 78; who was operated on November 14 for cataract, jumped from a window in St. Luke's Hospital, November 24, sustaining injuries from which he died shortly after.

Joseph Francis Berghoff ⊕ Butte, Mont.; John A. Creighton Medical College, Omaha, 1913; aged 33; a member of the staff of the Montana State Hospital, Warmsprings; died in St. Ann's Hospital, Butte, November 17, from pneumonia.

Capt. Joseph E. Dudenhofer ⊕ **M. C., U. S. Army,** Erie, Pa.; Jefferson Medical College, 1911; aged 30; on duty with the American Expeditionary Forces in France; was killed in action, September 17.

Died in the Service
in France
Capt. Joseph E. Dudenhofer, M. C.,
U. S. Army, 1888-1918

Harmon Jackson Wall, Richland Center, Wis.; Rush Medical College, 1880; aged 74; a member of the State Medical Society of Wisconsin; a veteran of the Civil War; died at the home of his daughter in Milwaukee, November 14, from pneumonia.

Lieut. Malcolm Cunningham ⊕ **M. C., U. S. Army,** Chicago; Chicago College of Medicine and Surgery, 1917; aged 25; on duty with the 76th Spruce Squadron, Astoria, Ore.; died at his post, October 8, from pneumonia following influenza.

Herbert Clargo Mills, Berkeley, Calif.; College of Physicians and Surgeons of San Francisco, 1901; aged 39; a member of the Medical Society of the State of California; died at his home, October 22, from pneumonia following influenza.

John Millington, Greenwich, N. Y.; University of Michigan, Ann Arbor, 1873; aged 71; a member of the Medical Society of the State of New York; at one time health officer of Washington County; died at his home, November 3.

Frank Joseph Stoll, New York City; University of Klausenburg, Hungary, 1909; aged 34; who volunteered to assist in the influenza epidemic in Pottsville, Pa.; died in that city, October 20, from pneumonia following influenza.

David Ralph Houston, Miami, Fla.; Manitoba Medical College, Winnipeg, 1909; aged 35; for several years a practitioner of Dominion City, Manitoba; died at his home, November 15, from pneumonia following influenza.

Robert Z. Ingersoll, Seymour, Ia.; Keokuk Medical College, College of Physicians and Surgeons, 1902; aged 41; a member of the Iowa State Medical Society; died at his home, October 22, from pneumonia following influenza.

Lieut. Grover Carlisle Price ⊕ **M. C., U. S. Army,** Judson, Ind.; University of Louisville, Ky., 1909; aged 30; on duty with the American Expeditionary Forces in France; died at Toul, France, October 30, from bronchial pneumonia.

Wilson B. Shelton, Bingham, Ill.; (license, years of practice, Illinois, 1888); aged 75; a member of the Illinois State Medical Society; and a veteran of the Civil War; died at his home, November 4, from cerebral hemorrhage.

Malcolm Donald MacNab, Chicago; Rush Medical College, 1895; aged 47; at one time a member of the Illinois State Medical Society and Physicians' Club of Chicago; died at his home, November 27, from a gunshot wound.

Lieut. Timothy Gibson Sellew ⊕ **M. C., U. S. Army,** Marietta, O.; Medical College of Ohio, Cincinnati, 1901; aged 43; on duty at Camp Grant, Rockford, Ill.; died at that place, October 20, from heart disease.

Margaret Allen Judge ⊕ Erie, Pa.; Woman's Medical College of Pennsylvania, Philadelphia, 1910; aged 39; died at Hamot Hospital, Erie, Pa., November 22, from influenza.

Edward A. Butts, Washington, D. C., Georgetown University, Washington, D. C., 1873; aged 72; for many years a pharmacist and manufacturing druggist; died in his apartments, October 22, from pneumonia.

James Stewart Doubleday ⊕ New York City; University of Virginia, Charlottesville, 1893; aged 43; associate physician to the Southampton, L. I., Hospital; died at his home, November 14, from pneumonia.

Lieut. Clinton Virgil Reed ⊕ **M. C., U. S. Army,** Three Forks, Mont.; Rush Medical College, 1914; aged 29; on duty with a medical unit in England; died recently from pneumonia following influenza.

Albert Garfield Porter ⊕ Terre Haute, Ind.; Indiana University, Bloomington and Indianapolis, 1909; aged 38; police surgeon of Terre Haute; died at his home, October 29, from pneumonia following influenza.

William Madison Patterson, Egan, S. D.; University of Illinois, Chicago, 1902; aged 49; for some time editor of the local paper; died at his home, about November 13, from pneumonia following influenza.

Paul Orcutt Miller, Deer Lick, Pa.; Jefferson Medical College, 1915; aged 29; formerly of Warren, Ohio; died at the University of Colorado Hospital, Boulder, November 18, from pneumonia following influenza.

John Gustaf Swensson, Portland, Ore.; State University of Iowa, Iowa City, 1897; aged 42; a member of the Oregon State Medical Association; died at his home, November 22, from heart disease.

Lieut. Millard Cressy Clark ⊕ **M. C., U. S. Army,** Bethlehem, N. H.; Tufts College Medical School, Boston, 1917; aged 25; died at Camp Gordon, Ga., September 29, from bronchopneumonia.

Ernest Boston, Palacios, Tex.; Barnes Medical College, St. Louis, 1899; aged 43; a member of the State Medical Association of Texas; died in Owensboro, Ky., November 10, from pneumonia.

Lieut. Alfred Johnson ⊕ **M. C., U. S. Army,** Clyde, Kan.; St. Louis College of Physicians and Surgeons, 1907; aged 39; on duty at San Francisco; died at his home, November 6, from influenza.

John L. Poppe, Haley, N. D.; University of Christiania, Norway, 1903; aged 35; died in St. Luke's Hospital, Aberdeen, S. D., October 27, from double lobar pneumonia following influenza.

Lieut. Leslie James Phillips ⊕ **M. C., U. S. Army,** Weyerhauser, Wis.; Queen's University, Kingston, Ont., 1912; aged 30; is reported to have died recently in France, from pneumonia.

David J. Mercer ⊕ Poe, Ind.; Fort Wayne, Ind., College of Medicine, 1901; aged 39; died in the Lutheran Hospital, Fort Wayne, Ind., November 20, from pneumonia following influenza.

Isaac Brown Jordan, Hope, Ark.; Meharry Medical College, Nashville, Tenn., 1913; aged 32; a colored practitioner; died at his home, October 10, from pneumonia following influenza.

Claude Baxley, Baltimore; University of Maryland, Baltimore, 1860; aged 80; while crossing a street in Baltimore, October 18, was struck by an automobile and instantly killed.

Angeline Mildred Lemon Dumbleton ⊕ Detroit; Cleveland College of Physicians and Surgeons, 1908; aged 31; died at her home, November 7, from pneumonia following influenza.

James R. Hughes, Atlanta, Ga.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1913; aged 36; died at his home, October 12, from pneumonia following influenza.

Robert S. Miles, Tacoma, Wash. (license, Minnesota, 1900); aged 77; formerly of Glencoe, Minn.; a practitioner since 1868; died at his home, November 16, from pneumonia.

Mary Powell Sook Thompson, Cleveland; Cleveland University of Medicine and Surgery, 1880; aged 70; died at her home, November 9, from carcinoma of the liver.

Lieut. Albert Frederick Ostwald ⊕ **M. C., U. S. Army,** Buffalo, N. Y.; University of Buffalo, N. Y., 1911; aged 35; died at his home, November 8.

George P. Hemm, Hays, Kan.; St. Louis University, 1907; aged 36; died at his home, October 10, from pneumonia following influenza.

Lewis Jerome Murphy, Los Angeles; Medical College of Indiana, Indianapolis, 1903; aged 41; died at his home, recently.

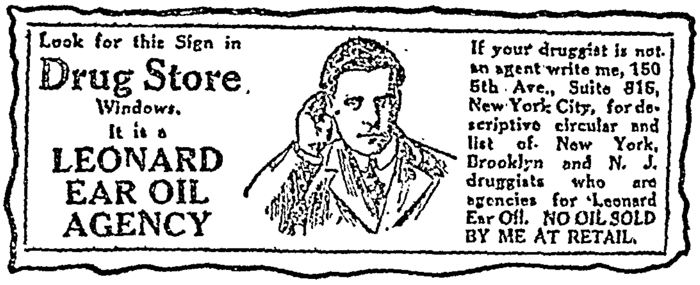
The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

LEONARD EAR OIL

Another Deafness Cure Humbug

"Leonard Ear Oil" is an alleged cure for deafness, sold by one A. O. Leonard of New York City. The present method of exploiting this nostrum is comparatively new. A few years ago Leonard was engaged in a mail-order business of selling his "Invisible Antiseptic Ear Drums." At that time his "Ear Oil" was an accessory to his "Ear Drum" trade, and constituted the "repeater" part of the business. More than four years ago, the Propaganda department collected Leonard's series of follow-up letters; these were of the usual medical mail-order fake type, with the accompanying testimonials, bulletins, etc. The price first asked for one of the "Invisible Antiseptic Ear Drums" was $5.00, which included, also, enough "ear oil" to last one month. Additional "ear oil" came "at $1.00 per bottle, for the personal use of those who purchase the drums." Before the follow-up series was complete, the price had been reduced to $2.50. The final letter contained an offer to send a bottle of Leonard's Ear Oil for $1.00, nothing being said about the "Invisible Antiseptic Ear Drum." In fact, the last letter of the series would lead its recipient to infer that the "Ear Oil" was the only thing necessary to cure deafness.



Look for this Sign in Drug Store Windows. It is a LEONARD EAR OIL AGENCY

If your druggist is not an agent write me, 150 5th Ave., Suite 816, New York City, for descriptive circular and list of New York, Brooklyn and N. J. druggists who are agencies for Leonard Ear Oil. NO OIL SOLD BY ME AT RETAIL.

Like most mail-order quacks Leonard apparently sold the original letters received from prospective victims, after they had ceased to be commercially valuable to him. At any rate a company that makes a business of buying and selling the original letters of "suckers" offered for sale, under "Deaf Letters," more than nine hundred of A. O. Leonard's vintage of 1907-08, more than five hundred of 1909-10, and more than seven hundred of 1911-12.

During the past year or two, Leonard seems to have been putting the soft pedal on the "invisible ear drum" part of his business, and playing up his "ear oil" fortissimo. Moreover, instead of selling the stuff as a mail-order proposition, Leonard now does business through drug stores. This tendency on the part of mail-order quacks to abandon the mail-order method, and conduct their business through the retail drug trade channels is an indication of the growing appreciation on the part of quacks of the protective power of the post-office fraud order. Is it also an indication of the low standard of business ethics of certain retail druggists? Leonard Ear Oil is by no means the only mail-order medical humbug that has found it safer, and doubtless more profitable, to abandon the mail-order feature and split the profits with the retail druggist.

One wonders whether the postal authorities have, during the past few years, dropped a hint to Leonard that his methods were likely to bring him into conflict with the law. This suspicion is strengthened by changes that have taken place in the character of the Leonard advertising, during the past few years. In the past we were dogmatically assured that "Leonard Ear Oil removes the mucous, opens up the tubes," etc.; now with more circumspection we are informed that "The purpose of Leonard Ear Oil is to remove the mucous, open up the tubes," etc. In 1915 Leonard Ear Oil "restored" hearing, if one were foolish enough to believe the advertising: now "restored" has given place to "improves." A further comparison between the older and newer advertising claims will indicate the change from direct falsehood to inferential misstatement:

OLDER ADVERTISING	NEWER ADVERTISING
". . . the Leonard Glandular Oil, if applied as directed will *cure* the diseased or catarrhal condition. . . ."—[Italics in original.—ED.]	". . . the Leonard Glandular Oil, if applied as directed will *relieve* the diseased or catarrhal condition. . . ."—[Italics ours.—ED.]
"Rubbing this on the glands of my throat and back of my ears night and morning, thoroughly massaging it in, I have *cured* the catarrhal condition . . ."—[Italics in original.—ED.]	"Inserting this in my nostrils and rubbing on the glands of my throat and back of my ears night and morning, thoroughly massaging it in, I have *overcome* the catarrhal condition. . . ."—[Italics in original.—ED.]
". . . it, together with my Invisible Ear Drums, has *cured* literally thousands of cases of Deafness and Head Noises that were considered hopeless."—[Italics ours.—ED.]	". . . it, together with my Invisible Ear Drums, has *relieved* literally thousands of cases of Deafness and Head Noises that were considered hopeless."—[Italics ours.—ED.]
"The imported Oil used in this preparation successfully carries the *curatives* it contains, . . . through pores of the skin to the diseased parts and effects a *cure*."—[Italics ours.—ED.]	". . . the Imported Oils used in this preparation successfully carry the *remedies* it contains to the diseased parts and *remove the cause* of Deafness and Head Noises."—[Italics ours.—ED.]

Some months age the Department of Health of the City of New York purchased specimens of Leonard Ear Oil and analyzed it. The chemist reported in effect, that the stuff had essentially the following composition:

Liquid petrolatum	41.96 per cent.
Ammonium oleate (soft soap)	8.18 per cent.
Oleic acid	14.40 per cent.
Camphor	9.85 per cent.
Eucalyptol	11.07 per cent.
Alcohol	12.00 per cent.
Water	2.54 per cent.

This would mean that Leonard Ear Oil is to all intents and purposes liquid petrolatum with camphor, eucalyptol, etc., emulsified by aid of a soft soap produced from ammonia and oleic acid. Having determined the composition of Leonard Ear Oil, the Department of Health of the City of New York lodged a complaint against Leonard, who was arrested and arraigned before the Court of Special Sessions, and adjudged guilty of making false and misleading claims. On July 14, 1918, Leonard was sentenced to thirty days in jail or to pay a fine of $250.00. Of course he didn't go to jail.

The Health Department of New York City went still further in protecting the public against this humbug. It notified all druggists in New York City that "the continued sale of Leonard Ear Oil with these false and fraudulent statements attached, will constitute a violation of Section 116 of the Sanitary Code, and will subject the druggist so doing to prosecution." Moreover, the Bureau of Public Health Education of the New York Department of Health gave the facts publicity through its *Weekly Bulletin* and its *Monthly Drug Bulletin*, and prepared an exhibit which was placed in a window on a prominent street, exposing the Leonard fakery. The exhibit consisted of two placards used by the Leonard Ear Oil concern, with a bottle of the oil itself. Alongside the original bottle were placed two other bottles, one with material which the chemist's analysis showed the bottle to contain, and another showing a bottle of the same size containing water. Under these bottles appeared the following legends:

Bottle No. 1—"Leonard's Ear Oil. This preparation costs you $1.00. The Courts of this City have declared that the claims made as to the medicinal value of the preparation are false and misleading."

Bottle No. 2—"This preparation is, analytically, the same as 'Leonard's Ear Oil' and may be purchased at an ordinary drug store for about 20 cents."

Bottle No. 3—"This bottle contains water and is just as good as 'Leonard's Ear Oil' for deafness. The cost to you is only the price of the bottle."

This was last summer. Since that time another city—Cleveland, Ohio, which makes an effective attempt to protect its citizens from fraud in medicine—has taken action on the Leonard Ear Oil. Under date of November 4, the Commissioner of Health of the City of Cleveland issued an order to Cleveland dealers relative to the sale of the Leonard preparation. This order read as follows:

> "Informing retail dealers that Leonard Ear Oil has been examined by this department and found to be a misbranded product within the meaning of the laws applying to Cleveland in that the claims made for this product are false and fraudulent, and its sale is therefore contrary to the best interests of the public health of this city.
>
> "Dealers in Cleveland are hereby notified to discontinue the sale or offering for sale of Leonard Ear Oil."

As Leonard has ceased selling his stuff on the mail-order plan, he is no longer amenable to prosecution by the post-office authorities. As he doubtless is careful to avoid making false and fraudulent claims for his product on the *trade package*, he can not be prosecuted under the Federal Food and Drugs Act. There is nothing, however, to prevent him making all the misleading claims he wishes to, regarding his nostrum, if he confines these claims to circular matter or window displays distributed through drug stores, and newspaper advertisements. That is, there is nothing to prevent this, unless city or state health authorities follow the lead of New York City and Cleveland. Will they do it?

Correspondence

"A REGISTRATION FEE FOR PHYSICIANS"

To the Editor:—In THE JOURNAL, Nov. 16, 1918, p. 1629, is an article by Francis W. Shepardson entitled "A Registration Fee for Physicians." About the time I finished reading the article the mail brought me a letter from the author asking the names of three physicians of our county (Christian) to whom he might write and at the same time asking me to express my opinion of the measure. As it is a matter of interest and importance to the physicians of the state I am offering my comments through THE JOURNAL in the hope that others may be interested and, perhaps, express their approval or objections to the proposed measure.

Mr. Shepardson admits, by implication, that he is biased in his views and proceeds to point out the shortcomings of the medical profession in Illinois. He says that we have a very poorly organized profession; but aside from the one point of numbers he does not say in what manner we are lacking. Were he to investigate, he would probably find that in our state we are as well organized, both in the state and county organizations, as physicians are in other states.

He next points with pride to a formidable array of quacks and charlatans, who he seems to think are fostered by the medical profession of this state, regardless of the fact that through our state society we have begged the legislature from year to year for laws ridding the public of these various pretenders and as often have been turned down and the people of the state left to the impositions of the whole band. Why should he blame the medical profession for the existence of all these fake doctors when it is the laymen—the boasted "neutrals"—who through their representatives have passed the laws permitting them to exist and that, too, against the bitter protest of the medical profession?

He mentions the abortionist and other evil doers in our midst, but also points out that the prosecuting attorneys (neutrals, also?) have either refused to take up the cases or managed in some way to sidetrack them. He says that some of these cases failed because physicians were unwilling "to give testimony or to encourage deluded victims to give the department the legal use of the information given them in the quiet hours of confession," but he does not even suggest why these physicians refused to commit themselves.

When the state and the people sanction and legalize all these frauds, is it incumbent on the physician to injure himself when he knows he would only be censured for meddling?

Mr. Shepardson says there are more fakers and charlatans in medicine than in all the other professions and trades combined. This is probably true; and they flourish because the legislature, which represents the public, has persistently refused to give us laws to suppress them, and because the paid officials of the state are unwilling to perform their plain duty to the public, as Mr. Shepardson himself points out.

I might suggest right here that it is not by the sanction of the medical society of the state or any of its component societies that these evils exist any more than it is that nearly every newspaper carries advertisements of the most glaring frauds of "cancer cures," "consumption cures," "dissolving cataracts," etc. These advertisements are carried under state and national laws despite the most strenuous protests of the medical profession, although Mr. Shepardson, by implication at least, seems to think we are to blame for it.

In his comments on medical education I have no criticism, and the medical profession in general is pleased with the advanced standard of our medical courses. But this was not brought about by "neutral regulators" but by the advanced ideas of the physicians who constitute our medical societies.

Under the heading "Regulation of Practitioners," he points to nine different items under which revocation of license may be secured, but does not say how the proposed "regulation" of physicians is to secure such penalties or even the prosecutions for the offenses. There is no indication that the laws would be changed or that more direct evidence would be produced thereby for the prosecution of such cases, or that the prosecuting attorneys would change their habits in putting off these cases, as mentioned above. The quack who goes from town to town advertising to be a "specialist" on every disease to which human flesh is heir would be as free from prosecution as he now is; and if there are to be prosecutions at all, they will have to be made in the same manner as they now are, to wit: The physicians or others must lay in the complaint and furnish the evidence.

Mr. Shepardson points out that since the first registration law of 1877 went into effect there have been 29,936 individuals licensed, and adds, "How many of these licenses are active at the present time nobody knows." This is, no doubt, true; but would this annual registration correct the matter? Many have died, some moved to other states, some retired, and a *few* had their licenses revoked. Some may be practicing under fraudulent registration and, if so, all they have to do is to send in their fee and get a renewal card which they may hang in their offices and point to with assumed pride when their patrons come in, and thus continue their illegal practice as before. Why, therefore, resort to the proposed annual registration when we have a much better, more economical and easier method of finding and reporting these impostors? By sending the lists of physicians as already recorded to the secretaries of the various counties the lists may be verified or corrected as may be, and a far more correct list obtained than by annual registration.

Those secretaries who have served a year or two, and most of them serve long terms, know more of the physicians in any particular county than any registration would find out in ten years, and at no expense at all unless it be a mere matter of postage. Secretaries are always ready to correct these lists, and usually know every physician in their county.

It is true, no doubt, that the lists in the directory of the American Medical Association are not always perfect, and the same may be said of the one from the state board of health; but they are probably fully as correct as the one under the proposed registration would be, and with equal care in compiling and cooperating with the county secretaries would be more so with the added opportunity of corralling those who registered illegally, as, for instance, when they are registered on a diploma or examination not their own; for when the board of censors of the county society recommends a man for membership in a county society, they inquire very carefully into his standing, his graduation, etc., and have a much better opportunity to do so than that afforded by simply the payment of a registration fee.

In the fourth item of "advantages" it is claimed that the state would have better control over unethical practitioners; but a registration does not give us a law to punish the offenders. It is easy enough to find the unethical and fraudulent practitioner. What we want and need is the means of getting rid of him, and there is nothing even suggested in Mr. Shepardson's article whereby this may be accomplished any better by registration than under present conditions.

As regards the fee of two dollars, that is not much; and if there were a prospect of getting results there is not a reputable physician in the state who would not gladly pay it and be the gainer thereby; but for the reasons given, it seems to me to be an entirely useless cumbrance of the law and an annoyance to the members of the profession. Nor am I alone in this view. While writing these pages I took a little time off to inquire what benefits were gained by those who were already "regulated." I made the rounds of the undertakers, the barbers, the dentists, the jewelers and the plumbers; and of all these only three persons thought there was any benefit at all and the rest promptly and emphatically said "no," and usually added that the only ones benefited by the annual registration were those who got the jobs of keeping the records and collecting the fees. One barber, only, thought there might be some benefit by limiting his profession against itinerants; but he could not mention a single instance to support his belief. One dentist thought there might be some benefit, gave the same reason the barber did, and cited one instance in which a dentist was excluded from practice in the state; but later in the evening he met me on his way home and said that the exclusion was due to the fact that he was not registered at all in the state and not that the annual registration had kept him out. I saw one plumber and he thought there "might" be some benefit in the registration, but could not mention any instance in which the benefit had actually been observed.

It is my firm belief that if we could only get the laws, and honest, efficient officials to execute them, there would be no need of any regulation by laymen, no matter how "neutral" they may be.

D. D. Barr, M.D., Taylorville, Ill.

EPIDEMIC INFLUENZA IN PRIVATE PRACTICE

To the Editor:—The pandemic reached Hartford about the middle of September, reached its greatest pace about September 28, and from then on raged fiercely until October 21, when it began to recede. The number of deaths was 586 resident and 137 from out of town. The population is estimated at 145,000, thus giving a death rate of 4 per thousand. The number of influenza cases was about 23,000.

The schools and theaters were not closed here, and from the manner in which the epidemic spread they apparently were not an important factor in disseminating the disease. The epidemic raged most intensely in the crowded tenement districts. Proportionately, the Jews were hit harder probably than any other group of peoples. They were affected first and in great numbers. The northeast section, populated by Jews, Russians and Italians for the most part, was in the grip of the epidemic for a week before it spread to the east side (adjacent), populated mainly by Italians and Russians. In the latter days of the epidemic the south end of the city had more cases than the other sections. The hospitals were overcrowded and able to admit only a small portion of the patients needing admission. An emergency hospital was opened about October 15. It did good work, but was really too late to do the most good.

The subjoined observations were made from approximately 500 cases seen in private practice. As elsewhere, the fatalities were chiefly among the 20 to 35 age group. Similarly the prognosis was better for those over 40. Elderly patients were rare. It was a question whether it was more frequent for a child or an adult to bring the disease into the family.

Epistaxis was common, occurring in from 10 to 15 per cent. of the cases. Some of these resulted in pneumonia. The headache and backache frequently persisted for three or four days. The temperature on the first day was between 101 and 104. A feature of the temperature was its variability during the day, rising and falling at irregular intervals. In the ordinary case the temperature persisted for from two to five days. Sweating was common even without medication or hot drinks. The bowels were inclined to be constipated. There was a general but slight enlargement of the lymph nodes. The spleen was not palpable. The pulse was relatively slow in many cases, but was not always so.

In regard to treatment, no particular drug had special virtues. Rest in bed, fresh air, light, nourishing food, plenty of water and open bowels were the main reliances. A simple expectorant cough mixture, sometimes with the addition of codein, sufficed for internal medication in the ordinary case. Alcohol rubs were soothing when the temperature was high. For the heaviness and soreness in the chest, home-made mustard plasters undoubtedly gave relief. The "fever and pain" powders or capsules, as were ordinarily prescribed, frequently only increased the prostration, and in a few cases in which the patient had taken a number of them, it seemed to prolong their convalescence. This type of medication was frequently more harmful for the patient than the pain for which it was intended.

In the pneumonias, stimulation did not seem to stimulate. It was rare to find pneumonia develop in a patient who took to bed at the onset of his influenza, and have it set in before convalescence, but it did occur. Pneumonia usually occurred after too early getting out of bed, or from too strenuous efforts after or during convalescence.

Three cases of the meningeal type of influenza were encountered. Prompt spinal puncture with withdrawal of excess fluid which was under pressure gave immediate relief. These cases were recognized by unconsciousness chiefly, with variable rigidity of neck, convulsions, involuntaries, dilatation of pupils and vomiting. In one of these cases, in which spinal puncture was delayed, recovery was slower than in the other two.

HARRY BERMAN, M.D., Hartford, Conn.

PREVENTION OF INFLUENZA BY OSMOTIC ACTION IN AIR PASSAGES

To the Editor:—The infection of influenza unquestionably enters the system through the nasal spaces and upper air passages. This fact is practically proved by a mode of disinfection and cleansing of those spaces and surfaces which I have suggested and used in the case of many thousand individuals who would ordinarily be considered likely subjects to infection. Infection was prevented in practically 100 per cent. when the treatment was properly used.

The tortuosities of the nasal and postnasal spaces and their great extent make the use of the many remedies suggested ineffective, because, however excellent they may be in themselves, they do not reach all the surfaces involved and they furthermore lack certain physical qualities necessary to invite a sufficient and strong osmotic action.

A powder composed of impalpable boric acid, 95 parts, sodium bicarbonate, 3 parts, and calomel, 2 parts, thoroughly triturated, is the basis of treatment.

With a good powder blower, this powder is freely blown into the nose, and will reach every recess in the upper air passages, and does not seem irritating to any extent. This powder, by abstraction of liquids from the moist surfaces, dissolves, excepting the calomel, and will shortly cause a mucoserous flow induced by osmotic pressure, and during this process the membranes involved are thoroughly washed and disinfected by virtue of the double osmotic current induced. This mucoid secretion can then be discharged, and the process repeated after from four to six hours. Ordinarily, the use of this powder once a day will suffice to keep the nasal membranes in fine condition and free from infections.

JAMES A. BACH, M.D., Milwaukee.

THE CIVILIAN PHYSICIAN'S SACRIFICE

To the Editor:—May I ask why as my husband was a victim on the long list of doctors who succumbed to the terrible epidemic last month no mention is made in any periodical or public newspaper of these noble fellows who gave their lives in fighting this disease? Are they not to be mentioned in any way as heroes?

The sacrifices of physicians in this section of our country was greater than the people of closely populated districts during the past four years of war can conceive, as the distance they must cover is great, and doctors are few. My husband for the past year has practiced alone in this county his nearest town being 28 miles away, the farthest, 75 miles. He could not enter the Army on account of being tuberculous. When he died he had worked night and day for two weeks *alone* trying to save people in this county.

Another tuberculous doctor from an adjacent county came over and took up the fight, leaving a little doctor in his place who left a tuberculosis sanatorium in El Paso, to aid the people. I am sure similar cases could be brought to mind over our country. Is there no memorial for these gallant men?

MRS. LONGINO, Fort Stockton, Texas.

THREE SIGNS OF SOME VALUE IN THE DIAGNOSIS OF UNUSUAL CASES OF INFLUENZA

To the Editor:—The last epidemic of influenza has been confined almost entirely to inflammatory changes in the respiratory tract. While it is true that there have been occasional instances in which the whole brunt of the disease has been borne by other systems, these could be diagnosticated only by inference as (1) the presence of the epidemic; (2) attacks of well-marked respiratory influenza in other members of the same family, or (3) previous similar attacks, unquestionably of influenzal nature in the same individual. Even here, in many instances, on close questioning, it could be ascertained that there was an occasional sneeze four or five days before the onset of the disease.

In these out-of-the-ordinary attacks, the nervous system was the one commonly involved. However, 95 per cent. of the cases seen in this epidemic involved the respiratory system, and the diagnosis was almost always made within two or three minutes after seeing the patient. Now and again in an isolated case of this type the question was raised in the mind of the practitioner "whether or not one was dealing with an influenza or with an ordinary head cold or coryza," such as is not uncommon at this time of the year. The absence of early rise of temperature and pulse and respiration changes in some of the influenza cases made this often a puzzling problem. Most physicians "played safe" and diagnosticated all of such cases as influenza. This was eminently fit and proper.

1. In a large number of true cases of influenza of the respiratory tract I have noticed a sign that may at times be of some help from a diagnostic standpoint. It has not to my knowledge been described before. It consists of a very marked redness of the opening of the salivary or Steno's duct, just opposite the second molar tooth. The punctum is usually swollen and raised above the level of the cheek, and the red spot is seen in the center. Mere swelling of the punctum has no diagnostic import. It may easily be inspected by placing a spoon handle in the side of the mouth and retracting it. If the sign is present on one side it is almost always visible on the other as well. It is not invariably present, but can be seen in at least 70 per cent. of the cases.

It has been present in most of the sporadic cases, and here is of very considerable value.

2. The presence of fine crackles at both bases of the lungs posteriorly near the vertebrae is prima facie evidence of influenza in a case in which there is a history of an acute onset. In old persons who have been lying down for some time, in cardiacs with broken compensation and in cachexia of any kind, this criterion is valueless, because such râles are commonly present without influenza.

3. After the disease has spent itself, frequently a harassing cough persists. This cough resembles whooping cough more than anything else. On listening to one such paroxysm without a history, it is almost impossible to make a diagnosis from early whooping cough. On inspection, however, one will in these cases find a redness over the arches of the palate. This is from ⅓ to ¼ inch in width; sometimes it extends only half way up on the sides and at other times it makes a complete arch. It is seldom or never missing in this type of cough due to influenza.

Incidentally, by touching the pillars and the nasopharynx with a silver nitrate solution, more good will be done than by the ingestion of many pints of cough mixture.

Thomas F. Reilly, M.D., New York.

GOVERNMENT RESPONSIBILITY TO THE STUDENT

To the Editor:—The government has taken over the military control of the medical schools, enlisted the students, and has agreed to pay their tuition fee, their board, and $30 a month. I understand that now that peace is in view the government is going to give this up, which is all right, but the students expect to have this year's teachings under the above terms, and now are not prepared to suddenly pay the expense for the balance of the term. So it seems to me that the government, even if it gives up the military control of all schools ought to carry out at least the financial agreement with the students until the end of the year. Not to do this would be a great injustice to some of the poorer students.

J. H. Carstens, M.D., Detroit.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

STATUS OF RESERVE OFFICERS IN DEMOBILIZATION

To the Editor:—Please inform me as to the exact status of the Medical Reserve Corps with reference to the Army. Was the Medical Reserve Corps abolished? Was there a Medical Reserve on Nov. 1, 1918, of any kind? Is there a Medical Reserve Corps for doctors and students separately?

C. R. Kessel, Morgantown, W. Va.

Answer.—As stated elsewhere in this issue, in the demobilization of officers of the Army those whose services are no longer needed will be given an honorable discharge. Such discharges will be a complete separation from the service. Opportunity will then be given to them to express their desire to reenter the Officers' Reserve Corps, Medical Section. Other officers who are qualified may enter the regular Army. The granting of new commissions will be dependent on individual fitness, eligibility and number of vacancies as provided by existing or future legislation. Although all of the officers of the Reserve Corps were originally commissioned for five years, commissioning for the period of the emergency was, it is reported, made by G. O. No. 73 which terminated the five year provision. This made all men officers of the Medical Corps. It has been reported that legislation will be presented to Congress for the reorganization of the Army whereby suitable arrangements may be made for commissioning in the regular Army and in the Officers' Reserve Corps men who have served in the present war. Under the National Defense Act of 1916 there was both an Officers' Reserve Corps and an Enlisted Reserve Corps so that medical students were made eligible for the Enlisted Medical Reserve Corps.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Alabama: Montgomery, Jan. 14. Chairman, Dr. S. W. Welch, Montgomery.

Arizona: Phoenix, Jan. 7. Sec., Dr. Allen H. Williams, 219 Goodrich Bldg., Phoenix.

Colorado: Denver, Jan. 7. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

Delaware: Wilmington, Dec. 10-12. Sec., Dr. H. W. Briggs, 1026 Jackson St., Wilmington.

District of Columbia: Washington, Jan. 14-16. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

Florida (E): Jacksonville, Dec. 16-17. Sec., Dr. G. A. Munch, 1806 Franklin St., Tampa.

Hawaii: Honolulu, Jan. 6. Sec., Dr. J. R. Judd, Honolulu.

Illinois: Chicago, Dec. 9-11. Mr. F. C. Dodds, Supt. of Registration, Springfield.

Iowa: Des Moines, Dec. 10-12. Sec., Dr. G. H. Sumner, Capitol Bldg., Des Moines.

Minnesota: Minneapolis, Jan. 7-10. Sec., Dr. Thomas McDavitt, 741 Lowry Bldg., St. Paul.

New Mexico: Sante Fe, Jan. 13. Sec., Dr. W. E. Kaser, East Las Vegas.

North Dakota: Jan. 7. Sec., Dr. G. M. Williamson, 860 Belmont Ave., Grand Forks.

Oklahoma: Oklahoma City, Jan. 7-8. Sec., Dr. J. J. Williams, Weatherford.

Oregon: Portland, Jan. 7. Sec., Dr. H. S. Nichols, Corbett Bldg., Portland.

Pennsylvania: Philadelphia, Jan. 7-9. Sec., Mr. Nathan C. Schaeffer, State Capitol, Harrisburg.

Rhode Island: Providence, Jan. 2-3. Sec., Dr. B. U. Richards, State House, Providence.

South Dakota: Pierre, Jan. 14. Sec., Dr. P. B. Jenkins, Waubay.

Utah: Salt Lake City, Jan. 6. Corres. Sec., Dr. G. F. Harding, 405 Templeton Bldg., Salt Lake City.

Virginia: Richmond, Dec. 10-13. Sec., Dr. J. W. Preston, 215 S. Jefferson St., Roanoke.

Washington: Spokane, Jan. 7-9. Sec., Dr. C. N. Suttner, 415 Old Nat'l Bk. Bldg., Spokane.

Wisconsin: Madison, Jan. 14. Sec., Dr. J. M. Dodd, 220 E. 2d St., Ashland.

District of Columbia October Examination

Dr. Edgar P. Copeland, secretary of the Board of Medical Supervisors of the District of Columbia, reports the oral and written examination held at Washington, Oct. 8-10, 1918. The examination covered 16 subjects and included 80 questions. An average of 70 per cent. was required to pass. Of the 7 candidates examined, 6 passed and 1 failed. Two candidates were licensed through reciprocity. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Georgetown University (1918) 79.2, 85.6, 88.4.		
George Washington University	(1918)	90
Howard University	(1918)	80.6
University of Maryland	(1917)	82.5
FAILED		
University of Nashville	(1893)	16

College	Year Grad.	Reciprocity with
LICENSED THROUGH RECIPROCITY		
Georgetown University	(1914)	Maine
Bowdoin Medical College	(1916)	Maine

Illinois June Examination

Mr. F. C. Dodds, superintendent of registration, Department of Registration and Education, reports the practical and written examination held at Chicago, June 3-6, 1918. The examination covered 10 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 232 candidates examined, 203 passed and 28 failed. One candidate did not complete the examination. The following colleges were represented:

College	Year Grad.	No. Licensed
PASSED		
Howard University	(1918)	1
Chicago Coll. of Med. and Surg.	(1915) (1917, 2); (1918, 68)	71
Hahnemann Med. Coll. and Hosp. of Chicago	(1918)	14
Loyola University	(1916, 2) (1917, 2)	4
Northwestern University	(1918)	52
Rush Medical College	(1918)	37*
University of Illinois	(1918)	20
Washington University	(1918)	1
University and Bellevue Hosp. Med. Coll.	(1916)	1
Queen's University	(1917)	1
University of Kharkov	(1914)	1

FAILED		
Chicago Hospital College of Medicine	(1915)	2
Chicago College of Med. and Surg.	(1917, 5) (1918, 7)	12
Jenner Medical College	(1910) (1911) (1917)	3
Loyola University	(1916) (1917)	2
Northwestern University	(1918)	1
Rush Medical College	(1918)	1*
Boston University	(1911)	1
University Medical College of K. C.	(1900)	1
Meharry Medical College	(1912) (1913) (1915) (1916) (1917)	5

*Degrees for 32 of these candidates were withheld, pending completion of hospital internship.

Book Notices

COMMOTIONS ET EMOTIONS DE GUERRE. Par André Léri, Professor agrégé à la Faculté de Paris. Préface du Professeur Pierre Marie. Paper. Price, 4 francs. Pp. 196, with illustrations. Paris: Masson et Cie, 1918.

When the war began, the French had a great advantage. They knew more of nervous diseases than any other nation and they had a greater number of trained observers in this department. Consequently, they more quickly sized up the situation and more promptly had a fairly adequate organization to handle nervously sick soldiers. Naturally they have gone farther than the rest and are in a position to teach. This is exemplified in the present small book, which is limited to what the author calls the *commotionné*, the *contusionné* and the *emotionné*. We may say that he treats of patients suffering from concussion and contusion of the central nervous system and the war neuroses. He has the great advantage of having served at the front, in the immediate rear and in a neuropsychiatric center of the interior. Each of the three classes of cases by no means presents the same clinical picture at the three different stations, and the author gives us the benefit of his unusual experience by considering each class of trouble (*a*) on the battlefield and at the first aid station; (*b*) at the evacuation hospital (à l'ambulance), and (*c*) at the base hospital or convalescent center. The descriptions are remarkably clear, and the illustrative cases cited are illuminating. It cannot be said that all of the opinions expressed are shared by the author's colleagues; but the book is fairly representative of French war neurology, which is the best that there is. It is condensed, is a small mine of information, and should be in the hands of every reader of French who is interested in what war (and other things) can do to the nervous system.

THE NORMAL AND PATHOLOGICAL HISTOLOGY OF THE MOUTH. Being the Second Edition of the Histology and Patho-Histology of the Teeth and Associated Parts. By Arthur Hopewell-Smith, L.R.C.P., M.R.C.S., L.D.S., Professor of Dental Histology, Pathology and Comparative Odontology, University of Pennsylvania. Volume I—Normal Histology. Cloth. Price $4.50 net. Pp. 345, with 264 illustrations. Philadelphia: P. Blakiston's Son & Co., 1918.

This volume is divided into three parts. The first contains chapters on Nasmyth's membrane, the enamel, the dentin, the cementum, structural modifications of the tissues, the dental pulp and the alveolodental periosteum. The second part deals with the oral cavity and its accessories, including the lips, cheek and tongue, glands, palate and tonsils; the maxillary and mandibular bones, and a group of minor structures, including the absorbent organ, the dental capsule, the gum and the mucous membrane of the maxillary sinus. The third part is devoted to the development of the teeth in mammals, fishes, reptiles and batrachians. The appendix has a note on the functions of the cells of the dental pulp and on the absorption of the alveolar process. The work is encylopedic in character, giving the views of many investigators on each subject. This makes it of value to those who are able to analyze the material for themselves, but is apt to confuse the average student. The work is strongly colored by the author's views, especially concerning Nasmyth's membrane, the cementum and the dental pulp. The author's statements in regard to the lymphatic vessels seem hardly justified in view of the work of Schytzer, and the more recent confirmation of his work in this country. The volume is well illustrated.

Medicolegal

Privileged Communications—Admissibility of Evidence

(Dodd v. State (Texas), 201 S. W. R. 1014)

The Court of Criminal Appeals of Texas, in affirming a judgment of conviction of defendant Dodd of rape in this case, wherein the death penalty was assessed, says that the defendant set up insanity as a defensé. A physician, an expert on insanity, who appeared to have been present at the trial as a witness, was called by the state in rebuttal, and objected to testifying because he had been employed by the defendant to make an examination of him with reference to his sanity, and that he desired to be exempt from the necessity of giving his opinion on account of the confidential relationship existing between him, a physician, and the defendant, his patient. The court, without objection from the defendant, excused the witness, and at the end of the trial the defendant requested the court to instruct the jury to disregard the incident just related. The defendant presented no authority sustaining the contention that there was error thus disclosed, and this court has found none. The physician was a witness, and the state's counsel appeared to have been within his rights to call him to testify, and so far as this court was advised, to require him to testify, so far as the inhibition of privileged communications touched the subject. The general rule is that communications between physician and patient in the absence of statute are not privileged. The courts recognize that there are many reasons for regarding the communications between physician and patient as privileged when the patient seeks the physician for medical aid, and in many states statutes have been enacted on the subject. It has been held, however, that when the consultation is not for medical aid, these reasons do not obtain. Whatever the rule, there is no statute in this state exempting such communications

When insanity is an issue, it is competent for the state to call witnesses to prove the conversations and conduct of an accused, not admitting guilt, while in jail as a basis for an opinion as to the sanity or insanity.

If evidence that the hymen of the prosecutrix had been previously ruptured by an operation was material and admissible, the proof of it should have been made by direct inquiry of her as to the fact. Her statement to a physician would have been hearsay, not competent to prove the fact, but available only to impeach the prosecuting witness if on inquiry of her she had denied the fact that the operation had taken place.

Test of a Hospital as a Public Charity and Why Exempted from Taxation

(Lutheran Hospital Association of South Dakota v. Baker, County Treasurer (S. D.), 167 N. W. R. 148)

The Supreme Court of South Dakota, in reversing a judgment that was rendered in favor of the defendant in this action to recover certain taxes levied against the property of the plaintiff and paid under protest, holds that the plaintiff was a corporation or society organized and conducted exclusively for charitable purposes, and that its property was being used exclusively for such purpose and was exempt from taxation, under the state statute providing that all property belonging to any charitable society or used exclusively for charitable purposes shall be exempt from taxation. The court says that the criterion in this class of cases seems to be that whatever is done or given gratuitously in the relief of public burdens or for the advancement of the public good is a public charity, and an institution founded as a purely public charity does not lose its character as such under the tax laws if it receives a revenue from the recipients of its bounty sufficient to keep it in operation; or, applying another test, if the object for which an institution is founded is the general public good, and not private gain, and it is so conducted that the public receives all the benefits of it, it is purely a public charity. Indefiniteness of beneficiaries is one of the characteristics of a charitable use. A public charity may be open to all mankind, or the officers, thereof may be empowered to select beneficiaries from designated classes of humanity. The fact that the plaintiff had a department for training nurses was not in conflict with its charitable purpose. It was just as necessary to have trained nurses as any other appliance. Common observation would say that one of the most efficient methods for procuring trained nurses would be to do your own training, so that no private profit resulted therefrom. So training, and having on hand at all times when needed, well-trained nurses, would improve the facilities of the institution for caring for the sick. The existence in a community of such an institution which admits, cares for, and gives medical aid to the pauper as well as the prince, without private gain to itself, is a public charity in the fullest sense. Very fortunate, indeed, is the community which has situated in its midst such an institution, organized and conducted as the one in question. It relieves the public from maintaining by taxation such an institution of its own. This is the basic reason for the exemption from taxation of the property of such institutions, when it is used exclusively for the purposes of charity.

Time from and for Which After Injury Medical Services May Be Compensated

(Cooke v. Holland Furnace Co. et al. (Mich.), 166 N. W. R. 1013, McMullen v. Gavette Construction Co. et al. (Mich.), 166 N. W. R. 1019)

The Supreme Court of Michigan says, in the first case, in which it reverses and vacates an award of the industrial accident board for compensation and for medical services rendered nearly a year after the date of the injury of the employee, that it was confronted for the first time with the question of whether the statute begins to run from the date of disability (or ascertainment and definite satisfaction that disability exists), or from the date of the accident, in the provisions of the employers' liability law that during the first three weeks after the injury the employer shall furnish, or cause to be furnished, reasonable medical and hospital services and medicines when they are needed, as to the time after the injury within which notice shall be given to the employer, and that within which claim for compensation shall be made. The court comes to the conclusion that it is compelled to hold, must hold, unless it resorts to judicial legislation, that the legislature by the two sections containing these provisions fixed the date of the injury at the date of the accident, and not some remote date thereafter, when the injured employee became definitely satisfied that he was disabled as a result of the accident.

In other words, as stated in the second case, decided on the same day as the first and wherein an award is also vacated, the court says that it held in the first case that the date of the accident fixed the date of the injury, under the workmen's compensation act, and that the industrial accident board was not authorized by the act to award and compensate the employee for medical and hospital services performed more than three weeks after the accident. The authority for such allowance by the board does not exist, except per force of the statute, and the legislative judgment has limited the allowance to such services as are performed during the first three weeks after the injury. Nor has the board authority to award as damages the amount paid for such services performed at a later date, on the theory, ingeniously advanced, that the failure to furnish proper medical and hospital services created a liability for the payment of such services so performed, which may be awarded by the board as damages.

8 Photochemical Effect of Certain Fluorescent Substances on Rennin. J. H. Clark, Baltimore.—p. 251.
9 Nature of Sensory Stimulation by Salts. M. Irwin.—p. 265.
10 *Secretory Pressure of Liver with Special Reference to Presence or Absence of Gallbladder. F. C. Mann and J. P. Foster, Rochester, Minn.—p. 278.

2. ***Effect of Epinephrin on Fatigue Produced by Injection of Fatigue Products.***—In this research the authors endeavored to determine whether epinephrin, which possesses the ability to increase the height of contraction and increase the decreased threshold irritability of a fatigued muscle, would counteract the fatigue produced by perfusing moderately strong solutions of fatigue substances through the muscle. It was found that epinephrin (0.5 to 1 c.c. of a 1:1,000 solution) counteracts the induced fatigue produced by the perfusion of fatigue substances such as sarcolactic acid, lactic acid and acid potassium phosphate through the muscle in identically the same way as it does the fatigue produced normally in active muscles. Epinephrin in some cases has no bettering effect. In these muscles it also has no ability to produce vasoconstriction.

3. **Effect of Epinephrin on Fatigue Produced by Perfusion of Acid Sodium Phosphate.**—Gruber found that epinephrin counteracts the fatigue produced by the perfusion of acid sodium phosphate as tested by the changes in the height of muscular contraction. In all cases in which a marked recovery was obtained, epinephrin caused an almost complete cessation of the passage of the perfusion fluid through the muscle.

5. **Nervous Reflexes in Experimental Traumatic Shock.**—The outstanding features in the results of Porter's investigation are as follows: Manipulation of the intestines in the spinal cat (a cat deprived of its brain) resulted in raising the threshold of the crossed extension reflex in all cases, and of the flexion reflex in roughly 50 per cent. of the experimental animals. Increase in threshold may be evident less than a minute after manipulation has commenced. Recovery may be complete or incomplete, prompt or delayed. It is more likely to be prompt and complete in the case of flexion than of crossed extension. The flexion reflex is never completely lost as a result of the manipulation; crossed extension often is lost. A case is described in which this did not occur until some minutes after the manipulation had ceased. The changes in reflex threshold are not dependent on a decrease in blood pressure; on the contrary, the blood pressure rises momentarily as manipulation starts, and this may coincide with the rise in reflex threshold. After the momentary rise, the blood pressure decreases steadily as the experiment proceeds, and the original reflex threshold may be recovered under a lower blood pressure than existed before the manipulation. The suggestion is made by Porter that if pain in the conscious animal could be measured during intestinal manipulation, it is probable that its threshold would show alterations roughly paralleling those of the reflex thresholds described in this paper.

7. **Experimental Surgical Shock.**—All of Mann's experiments were performed under ether anesthesia. By the manipulations of the various tensions of ether it is possible to parallel the various stages and signs of shock. Under high tensions the blood pressure is decreased and all the other symptoms follow. However, it is quite possible to saturate an animal with ether at a tension just slightly lower than that necessary to abolish the eye reflex and to produce an obtundity of the reflexes without decreasing the blood pressure to a shock level. It is possible to obtain such results with a certainty only when the ether is administered mechanically and is not dependent in any way on the respiratory efforts of the animal. In a study of the vascular and respiratory reflexes under various tensions of ether it was found that all the respiratory reflexes, except that which produces inhibition of respiratory movements, disappeared before the respiratory center failed. The excitatory respiratory reflexes disappear under a relatively high tenson of ether. On the contrary, instead of a depression of the inhibitory reflex being caused by ether, a relative increase, at least, is quite common. Thus it was possible under deep etherization, in some instances, actually to kill an animal by prolonged stimulation of the nerve fibers that inhibit respiration.

It was believed that this phenomenon might have some bearing on the shock problem; a more complete study of it was therefore made, and the following suggestive facts were obtained: The inhibitory reflex of respiration is decreased or completely abolished during periods of hyperpnea; the period of apnea following hyperpnea under light ether anesthesia is not increased by the stimulation of the nerves which inhibit respiration, and the inhibitory reflex is decreased or abolished during the period of increased respiratory movements in the first stage of asphyxia. An animal cannot be killed by reflex inhibition of respiration during the first stage of asphyxia. However, as asphyxia is prolonged and the respiratory movements begin to decrease, stimulation of inhibitory nerves will inhibit respiration and in many experiments produce sudden death.

In some experiments, while the time during which respiration is inhibited under deep ether is greatly increased over that under light ether, death cannot be produced. A slight period of asphyxia will increase the time of inhibition so that death will occur. It would seem that the lack of oxygen may be a factor. Inhibition of respiration under deep etherization frequently produces death very quickly. The blood pressure usually decreases at once and the heart soon stops beating. This result would seem to imply that death was due to or associated with other factors than asphyxia. However, a comparison of the curves in instances in which death was due to asphyxia under deep ether shows a close similarity to those found in the condition produced experimentally. The asphyxia under deep ether seems to explain the sudden decrease in blood pressure and stoppage of the heart, although an active process may be involved. Under light surgical anesthesia respiration is seldom inhibited for a very long time.

In a few experiments stimulation of the superior laryngeal nerves under an ether tension, slightly too low for surgical work, has produced a partial inhibition of respiration for as long as four to eight minutes. This period of inhibition is longer than that which produced death in several of the experiments under deep ether. Under the very low ether tension, however, blood pressure remained practically normal and death did not occur.

These results would furnish some support to the idea that the sudden death following inhibition of respiration under a high ether tension was mainly owing to a failure of the organism to compensate for the asphyxiation when saturated with a high ether tension. Ligation of all the structures to the limbs of a dog except the major artery, will usually produce all the signs of shock. The relative amount of tissues involved by these ligatures was on an average approximately 15 per cent. of the total body weight. The experiments show that a circulatory impairment following venous obstruction of the return of blood from the four limbs of an etherized animal is sufficient to produce the signs of shock.

10. **Secretory Pressure of Liver.**—The secretory pressure of the liver was found to vary considerably in various species of animals. The reason for this is not clear; there may be many causes; however, the presence or absence of the gallbladder does not seem to be one of them. The secretary pressure of the liver appears to be somewhat greater in unanesthetized animals than in those under an anesthetic, but since the data obtained on anesthetized animals were only comparative, the conclusion that the presence or absence of the gallbladder bears no relation to the secretory pressure of the liver is justified.

24 *Liberation of Internal Secretion of Thyroid Into Blood. J. M. Rogoff.—p. 193.
25 *Preparation of a Soluble Concentrated Product of the Thyroid Gland. J. M. Rogoff.—p. 207.

22. **Efficiency of Anthelmintics.**—Sixty-nine drugs or combinations were tested by Sollmann as to their anthelmintic property. He found that the highest vermicidal efficiency is possessed by substitutes that are not clinically available for this purpose; namely, mercuric chlorid, cupric sulphate, and mustard oil. Sollmann suggests that by virtue of this effect, anthelmintics doubtless often "expel" the parasite when the concentration does not rise sufficiently high to kill the worm.

23. **Action of Drugs on Different Parts of Intestine.**—This study was undertaken by Alvarez with the hope that light might be thrown on the physiology as well as pharmacology of the intestine. Other work convinced him that there are marked differences in the neuromuscular apparatus in different parts of the tract. Five segments excised from different parts of the rabbit's intestine were studied under identical conditions in warm aerated Locke's solution. Seventy-six substances were tested. Physostigmin, glucose, mercuric chlorid, pilocarpin, potassium chlorid and sodium bicarbonate stimulated all parts about equally, whereas alum, bile, calcium chlorid, cocain and ether depressed all parts about equally. Some of these drugs stimulate in small doses and depress in large; some depress or stimulate after an initial stimulation or depression; others affect one segment one way and another segment the other way. A number of substances stimulated or depressed one end of the bowel more than the other, while a few stimulated one end and actually depressed the other. Among the drugs which might steepen

the gradient were epinephrin, aloin, cascara, magnesium sulphate, sodium citrate, sodium bicarbonate and sodium chlorid. Among drugs which might reverse the gradient were digitalis, ergot, ipecac, potassium iodid, sodium salicylate and morphin sulphate. The depressant effects of alum, carbon dioxid, cascara, senna and sodium nitrite were usually more marked in the colon than in any part of the small bowel. Mercuric chlorid generally stimulated the colon less than the small intestine. Sodium salicylate sometimes stimulated the colon more than it did the small intestine. Benzene usually stimulated the small intestine and depressed the colon. Similar effects were obtained with lead acetate and phenol. They were observed less constantly with chloroform, copper sulphate, sodium chlorid and sodium citrate. Morphin generally increased the amplitude of the colonic contractions while it sometimes depressed the activity of the small bowel. Picric acid, in several experiments, markedly stimulated the colon and at the same time, depressed the small bowel.

24. **Liberation of Internal Secretion of Thyroid Into Blood.**—The object of this investigation was to determine whether it is possible to detect, in the blood coming from the thyroid, a substance whose physiologic activity corresponds to that of the gland. Rogoff reports the results of a preliminary set of experiments with blood obtained from the thyroid glands of three dogs, in which the tadpole reaction was employed. One dog, whose thyroid glands were rich in colloid and had a good iodin content, yielded evidence of an active secretion into the blood collected from the glands during massage and during stimulation of the cervical sympathetic nerve. Two dogs whose thyroid glands were hyperplastic and contained no detectable iodin yielded negative results.

25. **Soluble Product of the Thyroid Gland.**—The product "A" obtained by alkaline hydrolysis of normal thyroids of hogs, according to Kendall's method (1), was subjected by Rogoff to further hydrolysis in water acidified with hydrochloric acid. When the substance was completely digested the resulting solution was filtered through a Chamberland filter. To the clear filtrate was added hydrated aluminum silicate (Lloyd's reagent) and the mixture thoroughly shaken and filtered through paper. The hydrated aluminum silicate on the filter was thoroughly washed with water until all of the acid was washed out. The absorbed product was separated by slowly percolating through the material on the filter a dilute solution of ammonia in water until the percolate came through entirely colorless. The ammoniacal solution was then heated on a water bath and the ammonia driven off with the aid of a current of air passed through the solution. The resulting aqueous solution was reddish brown and on evaporation yielded an amorphous powder. This powder contained 13.44 mg. of iodin per gram of dry substance and the product "A" from which it was obtained contained 16 mg. per gram. A small quantity of the product was available for feeding experiments with tadpoles. This product showed very nearly the same degree of activity as the product "A" from which it was obtained.

45. **Cancer of Thyroid.**—One hundred and three cases of cancer of the thyroid were seen in the Mayo Clinic, a percentage of 1.6 of 6,359 cases of goiter, exclusive of the exophthalmic group. The cancer incidence, based on 14,456 patients with goiters, is 1.19 per cent. Of the 103 patients, 81.5 per cent. were more than 40 years old. Sixty-eight (68 per cent.) of the patients were females, thirty-five (35 per cent.) were males. The most important lesson to be drawn from an analysis of these cases, Balfour says, is the fact that in 46 per cent. no clinical manifestations of the disease were in evidence. This group shows by far the highest percentage (about 70) of patients free from recurrence at the present time. In other words, the great majority of apparent cures have occurred in those cases in which the malignant change was an unexpected finding. Total thyroidectomy was rarely performed in this group. In most instances the lobe containing the tumor and the malignant process was removed, but in many the enucleation of an adenoma was the procedure. The analysis showed also that when clinical evidences of cancer are present the results of surgical treatment are discouraging. Total extirpation of the gland appears to be indicated only when both lobes are grossly involved in the disease, and when past experience warrants surgical interference in the particular case. Recognizable involvement of cervical glands usually means that the time for surgical cure is past. Occasionally, however, just as the unexpected occurs in the treatment of extensive cancer elsewhere, an apparent cure is obtained. Gross involvement of trachea or esophagus is almost a certain sign against curability. In this series the average number of years of abnormal growth in the thyroid preceding the operation was 11.6. This Balfour regards as being proof positive of the advisability of the early removal of well-developed thyroid nodules.

47. **New Method of Percussion.**—The method described by Abrams embodies the principle of transsonance and is executed by continuous or intermittent direct percussion (without the interposition of a pleximeter) with the finger at the acromial extremity of either clavicle. In very fat individuals a pleximeter may be used and the latter struck by aid of a plexor with a soft rubber end. In the execution of the method cognizance is taken of the following components which make up the maneuver: (1) dulness; (2) palpatory percussion; (3) auscultatory percussion.

101. **Heart Murmurs in Recruits.**—When examining some thousands of applicants for the Naval Reserve, Cordeiro found that pulmonary murmurs far outnumbered all other forms of murmurs—perhaps ten to one. The majority of the pulmonic murmurs were found chiefly among runners, though they occur in all forms of athletics where there is a steady prolonged grind. The strain of a race is thrown almost wholly on the right heart. The left heart participates to a much less degree. The call is for blood and air in the lungs and the right heart endeavors to supply a double amount of the former. The pain in the side is a symptom of this abnormal effort. The pathologic history of these cases seems to be as follows: At first, after each abnormal dilation, the heart contracts to its normal size, or nearly so. But a physiologic hypertrophy accompanies these efforts and the pulmonary orifice, instead of contracting to its former dimensions, eventually overcontracts and becomes slightly narrowed. This may be furthered by the development of new muscular tissue about the orifice. These murmurs, while occurring chiefly among runners, were also found in footballers, basket-ball players, boxers, wrestlers and among rowing men. Baseball players seemed to be least affected. Many college boys, undeveloped and imperfectly developing, without proper food at home, and often without a midday meal, practice assiduously every afternon on a field. While their anemic systems are struggling with the burden of the rapid growth after puberty, they subject their hearts to the added strain of the track.

Another class of cases of pulmonary direct murmurs, which, while indistinguishable clinically from athletic murmurs, have been found less often, and present a picture of their own. These cases can be attributed to an incoordinated development of the great vessels relatively to other parts of the body. Cordeiro has called them tentatively, hypoplastic murmurs. They occur only among the poorer classes and seem to be clearly the result of insufficient nutrition. There is usually a weedy growth in which the nutrition seems to be expended wholly in increasing the length of the body while the other parts remain stationary—notably the great vessels. The rule in such cases is that the subjects are very much under weight for their height—20 to 40 pounds underweight. Their complexions and skins are pasty and pimply, in marked contract to the clear skin of health, in which specimens there are never heart murmurs.

As a result of his investigation, Cordeiro is convinced that athletes, professional and amateur, are of distinctly less value from a military point of view than the average normal man. He suggests that one of the reforms springing out of this war will be—not the abolition of athletics, but a revision of the present athletic system. Physical exercise from a recreational and hygienic point of view is necessary, but beyond that point is a waste of time and may be injurious. Track athletics among boys he regards as criminal, and among their elders is of no value to the participants or the community, but on the contrary tends to spoil what would otherwise have been good military material.

103. **Athletics and Their Relation to War.**—Luby draws attention to the fallacies of our athletic system as developed up to the present time. He points out the uselessness of the object sought, and asserts that there was no gain but rather serious loss to those who participated in athletics in the past. He pleads for a radical change in methods and objectives in the athletics of the preparatory school, the college, and the university. He says that one of the most serious faults of our present athletic system, a vicious, pernicious system, if ever there was one, is the necessity for haste. Trainers work feverishly and anxiously to develop a winning team. They must develop such a team at all costs because failure means the loss of a job. Medical men and, to a certain extent, military men recognize that there is something wrong with athletics as now conducted in America. If boys are allowed to follow the pernicious course which begins in the grammar school or preparatory school and ends only with the university, they must pay the price, as their predecessors have done. To neglect the most careful athletic development of boys is to sap the very roots of strength and vitality in the future material of the Army and Navy.

While it is generally admitted that military training has considerable incidental advantages from the point of view of health, it would seem that the first thing to be considered is the universal physical training of boys. The plan proposed by Luby is as follows: All branches of athletics must be reclassified on the basis of their effects on the heart and other vital organs, and not on the basis of popularity and commercial advantage. In the grammar school the form of athletics to which a boy could be assigned or in which he would be permitted to engage in would depend on (1) his family history; (2) his personal history, having regard especially to previous illnesses endured; (3) his physical status; (4) his particular type, height, weight, etc., in relation to age, etc. Every class should have its specially prescribed athletics, both physical and tactical, and under no circumstances should a lad be allowed to engage in competitive sports assigned to a class above or below his own. A physical examination would mark his entry and exit from a class and he would be marked for development of body and for ability to perform the various tactics. While in the grammar school a chart would be begun for him which would accompany him throughout his educational career.

As the boy passes on to the higher school there should be a reconsideration of his individual record and his family history. A physical examination should be made and his chart and previous athletic work considered. There should be athletic classes and all members of a school or college should participate, except when exempted for physical disability. Outside competitions with other schools would be reduced and the competitive idea find its illustration principally in interclass games. Work in the gymnasium should accompany and parallel the work done in teams and athletic games. Where students show beyond all reasonable doubt a real and permanent improvement in body and an increased ability to participate in various branches of sport they should receive credits at the hands of the college authorities in the same way that credits are given for scholarship.

All athletics of the more strenuous type and all those contests which inevitably induce even temporary exhaustion must be abolished. Mass competition, such as that in which a class would participate as a whole, is to be encouraged. New feats of prowess should be introduced. There should be walking contests, wall-scaling contests, obstacle raising, hurdling, shorter relay events with increased personnel, more soccer football, shot putting with a lighter shot, etc. The athletics of today must be remolded and their object clearly defined. Athletics can have no better purpose than to develop a robust and healthy boy who, though he may not be an interscholastic champion or sought after by the larger colleges as likely to increase their fame, will nevertheless enter on his life work with a symmetrical, fully developed body, capable of resisting disease and of enduring physical strain. For such a young man the training camp, the transport, and the trench will not contain the threat of death from disease before his grapple with the enemy.

Reports from General Pershing's Army showed that the highest mortality from communicable disease was in the National Army and the lowest on the Regular Army. Luby believes that the variation in susceptibility can be ascribed directly to the variation in the time of preparation and development which these different units have enjoyed, the development of the National Army having been characterized by intensive training and high speed. He believes further that the accumulation of fatigue substances from overtraining for lengthy periods without proper attention to the time element brought about a condition analogous to that seen in the stale athlete, and it is not to be wondered at that the overtrained soldier should be particularly liable to pneumonia, scarlet fever, influenza, etc. Luby's study of soldiers on transports confirmed this belief.—The men were trained "too fine!"

106. **Dengue at St. Thomas, V. I.**—Lane has made a careful analysis of cases seen during an epidemic of dengue which suddenly made its appearance among the Americans who had been on St. Thomas Island three to eight months. These cases presented some peculiar features. The immediate source of the infection was unknown. The important feature, however, was the agent carrying the infection. The *Stegomyia calopus* is practically the only mosquito seen and inhabitating the localities where the disease was most prevalent, and the only place where the mosquito bite seemed to do any damage. The mild character of the bone pains was characteristic. Involvement of the lymph glands, in many cases, was quite severe. No breaking down or suppuration subsequently has been noted. Not one set of glands but all the large superficial glands throughout the body were involved. Epistaxis, although it occurred in only 10 per cent. of the cases, was very severe and difficult to control. Pain on forced motion of the eyeballs was the principal cause of the symptoms described by the patient as "headache" or "pain in the eyes." The pain was only elicited on extreme motion. Hyperesthesia, of a most intense variety, was noted when the shoulder was unconsciously touched by the examiner. Vasomotor phenomena occurred from the sixth to the eighth day, causing a cyanosis and coldness of the arms, hands, lower legs, and feet in about 17 per cent. of cases. The disappearance of the eruption was followed in about twenty-four hours by a quite severe and long-continued desquamation, accompanied by intense itching at times, a sensation as of swelling of the hands and feet, and a continual and profuse sweating of these parts. Blood examination did not show on the average the very low leukocyte count and the discrepancy in the differential count usually acredited to dengue, yet these findings were sufficiently marked in a number of cases to accord perfectly with other descriptions. These blood findings depended largely on the severity of the attack.

A very disturbing feature in the convalescence, from the patient's standpoint, was the inability to relish food due to the bad metallic taste that everything had, although the appetite was quite keen. All the ordinary work could be performed without any difficulty, but the least extra strain, such as fast walking or going up hill, brought on an intense weakness and fatigue which had not been present before the fever and which it took some days and, in many cases, weeks to overcome. In most cases immunity seems to hold after one attack, but about 5 to 8 per cent. of the patients had a recurrence three weeks to several years after the original attack.

The epidemic gradually faded out. With the decrease in rainfall it had almost disappeared. Only an occasional individual who had just arrived would become infected. During the dry season when mosquitoes were very few, dengue was practically absent. The control of the mosquitoes and their breeding places has improved conditions to a slight degree, but the inability to obtain screening for the town, the lack of a properly trained corps of sanitary inspectors, and the difficulty in educating the people (natives) do not give much hope of freedom from dengue in the near future.

2. **Injection of Soluble Cinchonin Salts in Malaria.**—Experiments were made by Rogers to ascertain the rapidity and completeness of the absorption from muscle of quinin and cinchonin bihydrochlorid, respectively. In animals killed twelve hours after injection, 88 mg. of absorbed alkaloid were recovered from the organs in the case of the cinchonin sal., as compared with only 30 mg. in the quinin animal, showing approximately three times as great absorption in the practically important first twelve hours. On the other hand, 80 mg. of the precipitated quinin was recovered from

the muscle after twelve hours, as against 40 mg. of precipitated alkaloid in the cinchonin animal. At the end of twenty-four hours 65 mg. were recovered locally from the quinin animal against only 30 mg. from the cinchonin one, while 65 mg. were recovered from the organs of the cinchonin animal (where the alkaloid would come into contact with the malarial parasites) against 26 mg. in the quinin one. At the end of seventy-two hours the organs only showed 2 and 8 mg., respectively, showing that absorption must have now nearly ceased, and most of the drug, had already been eliminated from the body, presumably through the kidneys. The injected muscle now showed no less than 28 mg. of precipitated quinin still remaining in it, against only 10 mg. of alkaloid in the cinchonin animal, thus indicating that the absorption of the cinchonin salt was much more complete at the end of three days than of the quinin one. This fact, taken with the three times as rapid absorption during the first twelve hours of the cinchonin bihydrochlorid, indicates that the latter is far superior to quinin bihydrochlorid when given by the intramuscular route with a view to rapid absorption and action in a severe malarial infection.

The clinical effect on the animals was even more striking, for whereas the animals injected with the quinin salts appeared to suffer from no definite symptoms of poisoning, the cinchonin animals, on the other hand, became violently convulsed within half an hour of the injection, indicating very rapid absorption of the drug, a relatively very large dose having purposely been given.

In the treatment of human cases, the acid hydrobromid has been mainly used for intravenous and the bihydrochlorid for intramuscular and subcutaneous injections. By each method of injecting the cinchonin salts, rapid disappearance of both the fever and of the parasites from the peripheral blood was obtained in all three varieties of malaria. In the benign tertian and quartan cases the parasites always disappeared in one or two days, and in all but one the fever ceased within the same time, and in the remaining one within three days. In the malignant tertian variety the parasites generally disappeared within two days and always within three, and the fever ceased within the same period of time. The immediate results of the injection of the cinchonin salts were thus very satisfactory, and compare favorably, especially as regards the more serious malignant tertian variety, with those of adminsitering quinin by various methods in the army in England. In severe cases of malaria and during the prevalence of pernicious cases, as well as in patients who vomit orally administered quinin, Rogers suggests the further trial of intramuscular injections of 7.5, 10, and in adult males up to 15 grains of cinchonin bihydrochlorid (or in less severe cases, if preferred, the cinchonin acid hydrobromid, which produces less cinchonism) during the first few days of an attack of malaria, to be followed by a full course of quinin orally to prevent relapses.

4. **Quinin Prophylaxis in Malaria.**—The members of one group of rubber workers, the tappers, were given 10 grains of quinin each day for one year, and during that period no prophylactic quinin was issued to a second class of workers, the weeders, in order to determine the value of quinin prophylaxis against malaria. The result was entirely negative. The treatment gave no protection whatsoever against malaria.

5. **Sulphur as a Lice Destroyer.**—The trials forming the basis of this note were undertaken with a view to testing the efficiency of a process of fumigation as applied in the London Borough casual wards. The results of these experiments were entirely unsatisfactory, hence Bacot suggests reliance on heat, wherever possible, for the destruction of insect vermin, half an hour's exposure to a temperature of 55 C. being amply sufficient with either dry or moist heat, provided the clothing or other articles are suspended, and not bundled.

6. **Clinical Report of Rotunda Hospital.**—A total of 3,090 labors were attended by the hospital staff during the year. There were seven deaths. Two were due to hemorrhage, one to rupture of the uterus, one to eclampsia, one to cerebral hemorrhage, one to advanced pulmonary phthisis, and one patient was hopelessly septic when admitted. Among the complications were five cases of rupture of the uterus. A sixth case was sent into the hospital after the accident had occurred. Of the six patients, one mother died. Of nine cases of eclampsia, only one proved fatal, a mortality of 11 per cent. Besides these cases of eclampsia there were twelve of toxemia, the so-called pre-eclamptic state: all the patients recovered. Five labors were complicated bu uterine myoma, in three of which there was serious trouble including one death from hemorrhage. There was one case of mania. Forceps were applied 70 times. Version was performed ten times—three external, four bipolar, and three internal. External manipulation was twice employed to convert the breech into a vertex presentation. Bumm's subcutaneous pubiotomy was performed on two occasions, with satisfactory results as regards the mothers, but one child was stillborn, and the other died on the sixth day. Premature labor was induced five times, three times for toxemia, once for pelvic deformity, and once for mitral stenosis. Cesarean section was performed fifteen times, namely, in nine cases of pelvic deformity, in three of rupture of the uterus, twice for myoma, and once for anus vaginalis. The placenta was removed manually twenty-two times. Five cases of melena in infants were treated with horse serum, with one death.

21 *Use of Strychnin in Diagnosis of Malaria. H. H. King.—p. 116.
22 Romanowsky Staining. H. E. Shortt.—p. 124.

17. **Food Value of Groundnut.**—Wallis regards the groundnut or peanut as an especially valuable source of protein. It would seem that in India, where this legume grows in abundance, Nature had provided a cheap and efficient source of nitrogenous material to supplement the diet of the natives, which is rich in carbohydrates and poor in protein. The adoption of groundnut cake as a food is urged both on scientific and economic grounds. Wheat, oats, and several other cereals are markedly deficient in the so-called basic amino-acids, and groundnut cake contains the largest amount of these building stones of any known cake. To be palatable, easily digested and free from any objectionable taste, it requires to be properly prepared. The groundnuts as obtained after decortication must be washed free from grit, dirt, stones, etc., and have the red skin coating the kernels removed. The clean, white kernels are now subjected to hydraulic pressure to remove the arachis oil. After this expression, which should always be carried out in the cold, the groundnut cake still contains too much oil—between 9 and 10 per cent., or even as much as 15 per cent. Such a cake when ground up will yield a flour with a taste of the groundnut, which is slightly bitter. Further, it contains too much oil to be really serviceable for the making of bread or biscuits.

A large number of experiments were carried out by Wallis with such a cake, but it was found that the bread made from it was always too heavy. By warming the cake and then subjecting it again to hydraulic pressure, some of this oil is removed. The cake is now ground up, and yields an excellent flour, which possesses a slightly sweet taste, and is far superior in every way to the cake containing 10 per cent. or more of oil. The small amount of oil remaining, usually about 5 per cent., is, on the whole, beneficial, since it tends to preserve the flour, increase its nutritive properties, and makes a light and easily preserved biscuit. All objections to the groundnut as an article of food are thus removed, since the oil is the constituent responsible for any undesirable effects. Wallis suggests that in view of the shortage of the world's food supplies, both now and after the termination of the war, it would appear advisable to consider the utility of developing this industry with a view to the preparation of peanut flour on a large scale.

21. **Strychnin in Diagnosis of Malaria.**—Di Paca says that repeated doses of strychnin or berberin are useful in the diagnosis of malaria by increasing the number of parasites in the peripheral circulation. The dose of strychnin advocated is from 2 to 4 mg. by the mouth, or 2 or 3 mg. hypodermically every hour for four hours. The blood is then to be taken from the lobe of an ear at the end of the fourth hour. If it be true that strychnin has this effect, the observation is an important one, since it would materially aid the study of malaria and of malarial relapse. King tested this use of strychnin by comparing with each other blood slides taken before and after its administration. He found that strychnin in large doses (20 or 30 minims of liquor strychninae hydrochloridi, B. P., in five hours) will in half of the cases definitely contract a large spleen, but have no appreciable action on small spleens. In most cases it will not increase the number of parasites in the peripheral circulation. Hence, as a routine aid to diagnosis, strychnin has no place. King suggests that the blood pressure raising group of drugs, such as strychnin, be tried in the treatment of malaria in the early as well as in the late stages as an adjuvant to quinin.

27 Case of Primary Abscess of Spleen. J. Winterbotham.—p. 340.

23. **Long Continued Fever of Mesopotamia.**—The diseases to which the condition described has most resemblance are kala-azar, pulmonary tuberculosis, and malaria, either singly or a combination of kala-azar or malaria with tuberculosis. The condition has special resemblance to kala-azar, especially in its long continued pyrexia and in the leukopenia present and in the pigmentation. No Leishman-Donovan parasite, however, has been recovered from spleen or liver puncture either before or after death. Quinin, arsphenamin, antimony tartrate intravenously, and arsenic by the mouth seem to exert no influence on the course of the pyrexia. Moderate doses of potassium iodid have hitherto given most satisfaction. It is suggested that the disease will prove to be due to infection with a streptothrix-like parasite and therefore may be described as a "disseminated nocardiasis." The disease exhibits bronchitic, pulmonary or pleuritic signs at some period of its course. It may be fatal or spontaneous recovery may occur.

32 *Uremia After War Wounds. H. Reynès.—p. 308.
33 *Spirochetes in Influenza Sputum. De Verbizier.—p. 310.

31. **The Blood and Urine in Influenza.**—Patein comments on the surprisingly high urea content of the urine in his influenza cases.

32. **Uremia After War Wounds.**—Reynès found from 30 to 45 gm. of urea per liter in twenty-four hours in 30 cases of war wounds. About 210 analyses were made and they showed the gradual rise of the urea content of urine and blood, paralleling the gravity of the symptoms. The urea comes from the absorbed products of the disintegration of devitalized tissues, and by watching over the urea content of the urine it is possible to ward off serious uremia by giving hot sweetened drinks in abundance, with other means to stimulate diuresis. No nitrogenous food should be allowed, no milk, but saline purges should be given repeatedly. Other measures to combat uremia include warmth, rubbings, venesection, lumbar puncture, intravenous injections of sugar solutions, and thorough clearing out of all devitalized tissue, with ample drainage. In conclusion he reiterates that the "uroprognosis from the daily urea curve" is extremely important.

33. **Spirochetes in Influenza Sputum.**—Verbizier has found two varieties of spirochetes along with pneumococci, streptococci and probable Pfeiffer bacilli in the sputum of his influenza patients.

40 Tetragenus Sepsis Complications. Perfetti and Monziols.—p. 768.

34. **Walking Test of Functional Capacity of the Heart.**—Joltrain and Baufle comment on the instructive findings with the test of the heart which they apply. One hour after lunch the group being examined are sent for a walk over a certain course, from 2 to 15 miles long, under the surveillance of an experienced person. The walk is at a uniform pace, without resting, and the pulse is recorded before and after, and again as the individual reclines, perfectly still, the second, fourth, fifteenth, twentieth, thirtieth, forty-fifth and sixtieth minutes. No matter what the exertion, the tachycardia in a normal subject has always disappeared by the sixtieth minute.

Lyon Chirurgical, Lyons

May-June, 1918, **15**, No. 3

41 *Liver Abscesses in Macedonia. G. Cotte and Chifoliau.—p. 273.
42 *Sequelae of War Wounds of Chest. Pèhu and Daguet.—p. 291.
43 *Complications of War Wounds of Lung. Combier and Hertz.—p. 311.
44 *Pleurectomy for Wounds of the Chest. Roux-Berger.—p. 330.
45 *Extraction of Projectile in Lung. R. Olivier.—p. 339.

47 *Gastroduodenal Ulcer and Appendicitis. M. Dubard.—p. 356.
48 Laws of Healing of Superficial Wounds. R. Ingebrigtsen.—p. 363.

41. **Liver Abscesses in Macedonian Campaign.**—Among the fifteen operative cases, the abscess had already perforated in three cases, and in all the diagnosis had been made tardily, but seven of the men recovered. The symptoms from the abscess had been masked by malaria or dysentery. The cases teach the importance of systematic exploration of the liver in search of suppuration when the liver is found enlarged in a person with or who has had dysentery. The outlook for operative relief is infinitely better when it comes early, and radioscopy and puncture usually permit an early diagnosis. In one case it proved possible to clean out the pus pocket and suture it, with filiform drainage and healing by primary intention.

42. **War Wounds of Chest.**—Péhu and Daguet found three cases of unmistakable pulmonary tuberculosis among 146 men with war wounds of the chest reexamined from four months to three years afterwards. In two others there was

pleurisy of tuberculous origin. They were impressed by the frequent complete return to normal after extravasation of blood or a suppurative process. With tuberculous pleurisy, on the other hand, there is liable to be involvement of the diaphragm, etc., leading to irreparable lesions.

43. **Septic Local Complications of Wounds of Chest.**—The experiences in fifteen cases which are reported in detail show that it is possible to ward off chronic purulent pleurisy by clearing out the septic effusion in the pleura, rendering the pocket sterile by Carrel's technic for irrigation and drainage, and then suturing at the earliest possible moment. The war experiences have demonstrated the harmlessness of incision of the pleura, without fear of pneumothorax. Exercises to expand the lung are an important factor in the cure, especially exercising with the spirometer.

44. **Pleurectomy for War Wounds.**—Roux-Berger describes four cases of total pleurectomy, shelling off the stiff and thickened pleura, and fastening the lung to the chest wall to ensure its expansion. Three of the four men were completely cured; the fourth still has a small fistula left.

45. **Tardy Extraction of Projectile in the Lung.**—The projectile had been causing trouble in only two of the fifteen cases reported. The transpleural operation with artificial pneumothorax seems to be the preferable technic. The powerful retractors now used allow the ribs to be spread apart to give ample room for exploring the lung. The lung is easily brought outside the wound, the foreign body removed, and the airtight suture made.

47. **Gastroduodenal Ulcer and Chronic Appendicitis, Etc.**—Dubard found chronic appendicitis unmistakable in over 33 per cent. of 145 cases of gastro-enterostomy for ulcer. In private practice, this percentage is even higher. The frequency of such associated lesions of the gastro-intestinal tract explains the failure to cure of operations on one of the lesions, leaving the others still in a position to cause disturbance. They teach the necessity for careful exploration of the entire digestive tract. In 33 per cent. of his thirty-six laparotomies for ulcers and pyloric stenosis, the appendix was found diseased, as also in 45 per cent. of forty operative duodenal ulcer cases. He states further that 80 per cent. of his gastric ulcer cases presented evidences of pulmonary tuberculosis at the time, florid, torpid or healed. In nearly or quite all of them, pressure on the pneumogastric nerve in the neck on one or both sides was painful. He calls this the "sign of the pneumogastric," and explains it as a neuritis of this nerve, of pulmonary origin, and possibly reflected along the entire gastro-intestinal distribution of these nerves. This affords a predisposition to trophic disturbance, liable to elicit ulceration and certain other chronic inflammatory processes in the digestive tract.

53 Syphilis of the Pharynx. Bellin and Vernet.—p. 205.
54 Phlegmon Causing Jackson's Syndrome. H. Aloin.—p. 209.

49. **Ophthalmology in 1918.**—Terrien advocates the use of a mask to protect the eyes against scraps of shells, and has devised what seems to be a good model. He endorses Duverger's advice to retain the eyeball when the anterior portion only has been injured. In 150 penetrating wounds of the eye he succeeded in doing this in twenty-four cases, resecting down to sound tissue. He reviews among other works on ophthalmology published recently, Aubineau and LeNoble's study of nystagmus independent of eye and ear conditions; it must be classed with myoclonia. Also Weekers and Ferket's research on the multiple and diverse ocular disturbances liable to be encountered with icterohemorrhagic spirochetosis, including iritis, optic neuritis and herpes of the cornea. Every wound of the eye, it is emphasized, should be injected with a 1 per thousand solution of mercury cyanid, whether there is a foreign body present or not. This combats effectually the early infection in wounds of the eyes. If this had been done systematically in all the advanced stations, it is possible that the eyes might have been saved, in certain cases.

51. **Otorhinolaryngology in 1918.**—In Dufourmentel's review, he calls attention to Fay's statement that the disability from deafness does not depend on the acuity of the hearing but on the distance at which sounds are heard. Ability to hear the human voice is the gage of social impairment from deafness. The prognosis of deafness from shell commotion has proved favorable. The only treatment for war deafness that has proved effectual is by vocal reeducation and lip reading. Lombard's research on the sense of balance has established certain physiologic laws for antagonist movements with equilibration which have raised a number of new problems. A good illustration of some of these laws is afforded by the use of the balancing staff by the tight-rope walker. The physiologic laws he has determined impose certain attitudes for certain movements, and some of these attitudes have been perpetuated empirically in classic art. Among the recent progress in rhinology that has been realized is the appreciation of the pronounced tendency to spontaneous healing of war wounds of nasal sinuses. The mistake made at first was to regard and treat them like a sinusitis. Luc warns that a pointed trocar is liable to perforate the posterior wall of the maxillary sinus; a blunt instrument is better.

52. **Reconstruction of Nose.**—Seventeen illustrations show a number of devices to correct among other mutilations the loss of the tip of the nose. A triangle of bone and cartilage is cut extending sideways back of the nose, the straight side parallel with the upper jaw. This triangle is then swung around to bring the lateral tip on top. The flap then provides a normal outline for the nose.

61 Treatment of Influenza. G. Lyon.—p. 527.
62 *Present Status of War Surgery. G. Manoury.—p. 528.

55. **Antagonistic Action of Epinephrin and Pituitary Extract.**—Practically this same article was briefly summarized on page 1178, Oct. 5, 1918.

57. **Lining the Osteomyelitic Focus with Skin.**—Thévenard reports excellent results in the prompt healing of old and extensive inflammatory processes in bones by clearing out all devitalized tissue and lining with skin the deep groove left. The procedure is illustrated. The skin and subcutaneous tissue are incised to form square flaps each side of the bone focus. The bone lesion is cut to leave the focus as near a right angle as possible. A hole is bored through the soft parts and bone on one side to a point just above the inner angle of the gap in the bone, and a thread is drawn through. Then the loosened skin flap is drawn down into the gap to the lowest point, and is held there by tying the thread over a roll of gauze. The procedure is repeated on the other side, and the defect in the bone is thus lined smoothly with skin. The two flaps are fitted together where they meet at the inner angle, and may be held with a stitch. The threads are drawn only tight enough to hold the sets of gauze rolls in place.

60. **Influenza.**—Violle pleads for special hospitals for influenza patients, saying "Cases of fatal contagion of other patients already in the hospitals and left in contact with the influenza newcomers are already beyond counting, they are so numerous." It is equally important, he reiterates, to isolate, bacteriologically, influenza patients from each other. He advocates masks for all the healthy in contact with influenza patients, citing the favorable experiences with

masks in Manchuria during the epidemic of *pneumonic* plague.

He compares influenza with hog cholera as *instances of* infection by some one virus which opens the portal to another virus. In hog cholera, the invisible bacterium that unleashes the disease opens the portal to the paratyphoid bacillus. Without the latter there is no hog cholera, and yet we know that it is unable, alone, to induce hog cholera. Its presence is important both from the standpoint of *prophylaxis and treatment*, as the destruction of the paratyphoid bacilli seems to check the development of the still *unknown primal bacterium* of hog cholera. In influenza, the invisible virus causes such *extreme prostration* and has such toxic action that the ordinary microbes already present in the air passages or digestive tract rush into the gaps in the defenses. Nicolle calls these secondary invaders *microbes de sortie*. *Probably* even the *Pfeiffer* bacillus belongs in this group. All *varieties* and degrees of lesions may result, such as are possible when a *virulent, toxin-producing* and pyogenic microbe steps into a soil prepared in advance with ideal conditions for its rapid proliferation. One writer has said, "The reason why influenza kills, is because it strikes at the thorax." Meunier adds, *La grippe condamne et la surinfection éxécute.* The true microbe of influenza may have already disappeared by the time this superposed infection strikes home.

Violle reasoned that if the superposed infection could be warded off, influenza would lose its danger. In his region, the pneumococcus seemed to be mainly responsible for it, and he treated his influenza patients systematically with antipneumococcus serum in the same way as antitetanus serum is given the wounded. Each patient was injected in each thigh with 20 c.c. of antipneumococcus serum four hours after a preliminary injection of 1 c.c. of the same serum, and 4 gm. of calcium chlorid were given by the mouth. A hot compress was laid over the site of the injection. He says, "The results obtained were remarkable; it may even be advanced that pulmonary complications are averted by this means. But it is effectual of course only when the pneumococcus is the causal agent of the pulmonary complications. In regions where the streptococcus is involved, an antiserum for this would have to be used, or both. It seems as if the streptococcus was responsible more for the pleural complications, and the pneumococcus for the pulmonary." He also tried convalescents' serum but, as at least 100 c.c. are required for each patient, he turned to autoserotherapy, and this has given conclusive results, he says, in several cases. He drew the blood from a vein in the arm and reinjected at once the 20 c.c. under *the skin of the outer front of the thigh*. He adds that this can be repeated day after day without any inconveniences.

62. **Present Status of War Surgery.**—This is the presidential address delivered by Manoury at the French Surgical Congress which convened at Paris, October 7. He emphasized the abyss that separates the *surgery of the day* from that which prevailed at the time of the last congress of the kind, five years ago. (See recent Paris Letters.)

63 *Hexamethylenamin in Tuberculosis. Loeper and Wagner.—p. 305.
64 Necessity for Early Nephrectomy with Renal Tuberculosis. R. Uteau and M. Piollenc.—p. 305.
65 Gangrenous Phlegmon of Back of Hand. E. Chauvin.—p. 308.
66 *Adiposis Dolorosa and Lipomatosis. Bourdinière.—p. 309.

Sept. 14, 1918, **33**, No. 37

67 The Feebleminded at the Court Martial. J. Crinon.—p. 313.
68 *Epilepsy, Hysteria and Chorea in a Military Hospital. H. Damaye.—p. 315.
69 *Serum Anaphylaxis. J. Fièvez.—p. 318.

63. **Hexamethylenamin by the Vein in Tuberculosis.**—Loeper and Wagner declare that, in their experience, this drug injected intravenously in a daily dose *of 1.25* or *1.5 gm.* for about twenty days seemed to exert a *decided action on* the general febrile, toxic and septic reactions in tuberculosis, without any depressant action. It seems to reduce the toxicity of the infection, wherever the *infectious process* may be located. In one case described in detail, the sputum swarming *with tubercle bacilli*, remarkable improvement was realized under two series of seven injections by the vein, a total of *21 gm. of the hexamethylenamin*. The young man had *nephritis with* 5 gm. albumin and ureosecretory constant of *0.24, besides the tuberculous left* bronchopneumonia.

66. **Adiposis Dolorosa.**—In the case described the typical adiposis dolorosa developed in a girl of 16 whose *menses* had been suppressed for several months. The pains returned at *monthly intervals* and the clinical picture showed great improvement under ovarian treatment. After two years of suspension menstruation returned, and since then the paroxysms *of pain have been much less* pronounced. The pituitary region seems to be normal, as also the thyroid. In another case *the* young officer has small movable lipomas on the forearms, absolutely symmetrical. They developed at about 16, and there is nothing else pathologic to be discovered in the robust young man. The lumps are only slightly painful.

68. **Epilepsy, Hysteria and Chorea in Advanced Psychiatric Center.**—Damaye gives some examples of convulsions resembling epileptic seizures which developed after exceptional physical exertion, long day and night *marching or manual* labor. A very little alcohol, then, may be the last straw that brings on the convulsion. The effect of a wound or bombardment or getting gassed may also have *this effect*. Epileptics average as high in courage as others, other things *being equal. They are not infrequently* cited for gallantry. Some do heroic acts in a kind of impulsive manner like that in which they sometimes commit criminal actions. *Some* epileptics display symptoms resembling those of neurasthenia, and some who have been trephined present, in addition to all this, attacks of jacksonian epilepsy. In treatment, a quiet *environment, sodium* cacodylate and a milk-vegetable diet *were the main reliance.* In the great majority of the cases the epilepsy dated from early life but had been aggravated by campaign conditions.

69. **Serum Anaphylaxis.**—Fièvez has encountered in the last year fifteen cases of a mild anaphylactic reaction to a second *injection* of antitetanus serum or other serum. The intensely itching urticaria developed suddenly, twenty-four or thirty hours after the repeated injection, in some cases. In one case the interval was only ten minutes. Preventive *injection of calcium chlorid and epinephrin did not seem to* do any good. Although these reactions are not severe, yet their repetition *might prove somewhat serious*, and *nowadays* antitetanus serum is often injected several times as a man *may receive several wounds in the course of time.*

Correspondenz-Blatt für Schweizer Aerzte, Basel

Oct. 5, 1918, **48**, No. 40

70 *Influenza Epidemic. E. Bircher.—p. 1338.
71 Biology of Lice. B. Galli-Valerio.—p. 1341.
72 Development of Bothriocephalus. C. Janicki.—p. 1343.

70. **Influenza.**—Bircher reiterates that his findings in the prevailing epidemic pointed to invasion of highly virulent streptococci, and there was not the slightest evidence to prove that the Pfeiffer bacillus was the cause of the disease. The weather was never so hot or the region so dry and dusty as this summer. Fatiguing work seemed to afford a predisposition, as also the lymphatic-asthenic constitution. About half the cases in his district developed pneumonia. He was impressed with the large proportion of children affected, but he knew of no case in an infant and no severe case in persons over 50. *One robust* person showed the first symptoms at 4 p. m. and died before 10 the next morning. The findings in the lungs were not those of ordinary pneumonia, but resembled more those of pneumonic plague, as German clinicians have also reported. The pneumonia *mortality* was 10 per cent., and severe empyema developed in some of the survivors. In one week he performed ten empyema operations. Some of the influenza *patients* lost up to 20 kg. in weight in one week. Complications were frequent, antistreptococcus serum proved *ineffectual, but antipneumococcus serum* benefited where pneumococci were found present. In some cases the influenza seemed to induce a positive Wassermann reaction. The disease was exceptionally fatal in the pregnant.

Gazzetta degli Ospedali e delle Cliniche, Milan

Aug. 1, 1918, **39**, No. 61

76 Disturbances from Artificial Feeding of Infants. R. Costa.—p. 615.
77 Influenza. T. Di Giuseppe.—p. 616.

74. **Treatment of Pleurisy.**—Panto's routine practice in primary pleurisy with effusion is to aspirate from 80 to 100 c.c. of the effusion on alternate days, repeating three or four times, always at a different point; giving digitalis, sodium salicylate and theobromin according to the indications; painting the chest wall with iodin; a light milk and egg diet, and during convalescence, the hypodermic injection of an iodin and iodid solution (Durante's formula). The results have been highly satisfactory in the sixty cases he has treated by this method. The diuresis increased at once, the local relief in the chest was pronounced, and the fever rapidly subsided. The reaction to the mechanical irritation from the repeated puncture aids in the resorption of the effusion until all is gone by the tenth or fifteenth day. The recovery is more rapid the earlier the punctures can be applied.

75. **Peripheral Neuritis in Pulmonary Tuberculosis.**—Tarchetti has encountered ten cases of peripheral neuritis in men with pulmonary tuberculosis at a certain hospital, and he was able to trace it to a favorite prescription in vogue there containing aconite. The neuritis was evidently due to chronic aconite poisoning, as there have been no further cases of the neuritis during the six years since the aconite prescription was discarded. The prescription called for 0.008 gm. of the alkaloid in each hundred parts of the excipient.

85. **Malaria.**—Pezzi and Polti urge the necessity for intensive measures during the coming months to cure every case of malaria, so that none will be left from which mosquitoes may get infected next spring and summer. The diagnosis is the first thing now, and every practitioner, they reiterate, should be on the alert to detect malaria.

Riforma Medica, Naples

July, 1918, **34**, Rummo Memorial Number

90 A Gaetano Rummo. In memoria.—pp. 1-28.

Sept. 14, 1918, **34**, No. 37

91 *Adequate Dietaries. E. Maragliano.—p. 726; S. Baglioni.—p. 726.
92 *Atropin as Test for Tachycardia. G. Galli.—p. 727.
93 *Arthrotomy for Purulent War Wound of Knee. G. de Francisco.—p. 729.
94 *Resection of Auriculo-Temporal Nerve for Parotid Fistula. R. Ianni.—p. 731.
95 Nosography of Wounds of Chest. E. Aievoli.—p. 735.

91. **Adequate Dietaries.**—Baglioni replies to Bottazzi's recent publications on this subject, and Maragliano comments on the depressing influence exerted by statements as to the indispensability of certain proportions of certain foods which war conditions, etc., have shut off more or less completely for the present.

92. **Atropin Test for Paroxysmal Tachycardia.**—In a case suspected of malingering, four minutes after a subcutaneous injection of 1 mg. of atropin the pulse dropped from 90 to 73, and the respiration grew slower. Then, the forty-third minute after the injection, suddenly the pulse ran up to 215 and the respiration rate became much increased. The tachycardia lasted for forty-seven minutes and then gradually subsided to 75 by the end of the hour. Even with internal administration of 20 drops of a 1 per thousand solution of atropin it is possible to elicit a typical attack of essential tachycardia in the predisposed, but the interval is over an hour when given by the mouth.

93. **Arthrotomy for Purulent Knee Process.**—De Francisco extols the advantages of a posterior-inner counter-opening in the popliteal space with wounds of the knees requiring drainage. The drainage is much more complete with this than with the usual median popliteal incision, while it is free from the dangers of the latter. He applies it to supplement ample lateral arthrotomy. The incision, about 6 cm. long, is made between the tendons of the rectus muscle and of the semitendinosus. The synovial capsule is incised on the internal tuberosity of the tibia and posterior margin of the internal condyle of the femur, the incision carried up to its superior insertion, guided by the finger or sound introduced into the joint through the inner anterior-lateral incision. At the same time, the bursa of the semimembranosus is incised. The joint is thoroughly rinsed out with boric acid solution and the recesses wiped out with sponges, rinsing then with ether and again with hydrogen peroxid.

94. **Resection of Auriculotemporal Nerve to Arrest Parotid Secretion.**—Ianni reviews what has been published in Europe on this subject, and gives illustrations showing the physiologic basis of the operation. He performed the operation on a soldier with a long war wound of the parotid region that had healed except for a fistula from which saliva poured constantly. The nerve was resected through an incision the same as for ligation of the superficial temporal artery, the nerve being found just below this artery. He isolated the nerve all the way down to the parotid gland and then pulled on it and cut the central end. He thus succeeded in isolating a tract 4.5 cm. long, with the small glandular secretory ramifications. The saliva still poured from the fistula for a few days, but by the seventh day the fistula had completely healed, and no saliva issued from the mouth of the duct of Steno. The cure has been complete during the nearly two years to date. None of the persons who have been operated on by this technic experience any inconvenience from the loss of the parotid secretion, the other glands furnishing abundance of saliva.

98. **Nature and Prophylaxis of Acute Articular Rheumatism.**—Agote comments on the close analogy between the primary chancre and recurring manifestations in syphilis, the mosquito bite and the recurring febrile attacks in malaria, on the one hand, and the primary infectious sore throat and the recurring attacks of acute polyarticular rheumatism. All

three share a primary lesion and a tendency to recurrence, and are all probably of parasitic origin. It has been his experience that the attacks of acute articular rheumatism occur in spring and fall, never in the extremely cold or the extremely hot months. He has noticed further that the recurrences develop at the same season as the first attack. He cites some cases in which the subjects could thus foretell exactly when a new attack was to be expected. Treatment and prophylaxis, therefore, should be on the same principles as for syphilis and malaria, prolonged and preventive medicinal treatment when recurrence is anticipated. He orders 1 or 2 gm. of sodium salicyate daily during the month before the anticipated recurrence. If the season is very backward, he makes allowance for this. In case of gastric intolerance, he gives 3 gm. in an enema on retiring. When the rheumatism shows a little let-up, he gives the salicylate for a fortnight or month, then suspends for the same length of time and repeats until the rheumatism is conquered. A number of cases are cited in which under this prophylactic treatment there has been no return of the previously annually recurring attacks of the febrile rheumatism every spring. One boy of 14 had had six spring attacks, but has not had the disease since this prophylaxis was inaugurated.

100. ***Pathologic Anatomy of Rabies.***—Apphatic remarks that the filtrability of rabies virus seems to disprove any assumption as to the Negri bodies being the parasite of rabies. It is possible that the spores might pass through the filter—In any event, he declares, the time has come for revision of the problem of filtrable pathogenic viruses.

101. **The Blood with Amebiasis.**—Vaccarezza found the blood much concentrated in some of the twenty-five cases examined, as the result of loss of fluids. In thirteen, eosinophils formed less than 3 per cent.; in five, from 3 to 5 per cent.; in four, from 5 to 7, and in three, from 7 to 10.5 per cent. The differential count in each case is compared with the clinical course, etc.

102. ***Syphilitic Gastritis.***—The husband of the woman of 44 was an old syphilitic and she had had six abortions besides seven still living children. For three months there had been pain in the epigastrium three or four hours after eating, with other signs of an infiltrating gastritis, but the stomach shadow was normal although not flexible. The blood picture was of the chlorosis type, and under intravenous injection of an arsphenamin preparation, recovery was soon prompt, complete and permanent.

105. **The Syphilitic Eye.**—Merlo during the last three years has found that the Wassermann reaction and the course of the case invariably confirmed his diagnosis of syphilis based on the aspect of the eye alone. One eyelid droops slightly, and this unilateral ptosis is accompanied by slight strabismus and a peculiar mixture of vagueness and sadness in the glance. He recognizes the syphilitic by this means, having found this "syphilis eye" *common* in the secondary and tertiary stages of the disease. The eye probably shows the effect of the involvement of the meninges.

116 Bacteriology of Dysentery at Rio. E. Gomes.—p. 267.

111. **Protection of Children of Tuberculous Parents.**—Ferreira is president of the Liga Paulista contra la Tuberculose, and he was the leading spirit in introducing into Brazil a movement similar to Grancher's plan in France. (This was described in THE JOURNAL, July 6, 1918, p. 1.) He describes the fine results realized by this "Obra de Preservacão" at S. Paulo. In 1914 it had fifty-five children in its charge, from 4 to 16 years old. In 1916 the number was fifty-eight, and two more advisory clinics and two more sanatoriums are planned.

125 Lavage of the Stomach. J. L. Yagüe y *Espinosa.—p. 126.*

117. **Complications of Malta Fever.**—Camacho remarks that Malta fever is endemic in his district (Granada) and causes more morbidity than any other disease. It frequently masquerades as pulmonary tuberculosis, typhoid fever, chronic rheumatism or meningitis, or it may be responsible for inflammatory and suppurating processes in joints and long bones. He describes six cases of this kind in children and adults. Inflammation in the synovialis and around joints is so common that it must be regarded as a symptom rather than a complication. The most frequent localization is in the sacroiliac articulation, next, the hip and shoulder. The effusion in the joint is a pure culture of the melitococcus, and when suppuration follows it seems to act like a fixation abscess, diverting the septicemia and generating antibodies to such an extent that prompt recovery ensues.

118. **Factors of Cirrhosis of the Liver.**—Martinez reviews the various factors that have been suggested by others, and then analyzes in detail fifty-four cases from his own practice. Alcohol was unmistakably to be incriminated in 59.25 per cent. In the other cases alcohol could not have been a factor, but infectious diseases, malaria, syphilis, etc., tobacco, lead poisoning or thyroidism evidently had a share in the morbidity of the liver.

134 The Campaign Against Venereal Disease. A. M. Gimenez.—p. 56.

126. ***History of Epidemics of Influenza.***—Del Pont is professor of epidemiology at Buenos Aires, and his historical review of 125 pandemics of influenza shows that 50 occurred in the winter, 35 in the spring, 16 in the summer and 24 in the fall. The first reliably recorded epidemic was in 1173, while authentic accounts of plague are on record from 2,030 years before our era. Among the odd facts he relates is the history of a ship in 1781 on which influenza developed in mid-ocean—no cases having been known in the port from which it sailed. Every person on the ship was stricken, and when it arrived at Canton the disease was found epidemic there, the first cases having developed at about the same date in Canton and on the ship in mid-ocean.

129. **National Register of Criminals.**—Delfino urges a national central headquarters where the data for identification of each criminal can be kept filed for ready reference, and where the outcome of each criminal court trial is duly and promptly filed. The courts of the country thus can obtain the complete summary of the criminal's career to date, and thus be enabled to pass judgment with true justice in each case, discriminating between the occasional and the habitual criminal. The scheme proposed provides for quick action on each demand for data, the records to be accessible only to the duly qualified authorities.

130. ***Complications of an Otitis.***—Rizzi's patient was a man of 34 with postinfluenzal right otitis media from which devel-

oped thrombophlebitis with suppuration and septicemia, with an abscess in the cerebellum. The man was finally completely cured after a two years' course of treatment including four extensive operations and twenty-six punctures of the brain.

140 *Radiotherapy of Superficial Cancer. J. H. Kuijjer.—p. 734.
141 *Exploratory Puncture of Cancer. H. T. Deelman.—p. 744.
142 Influenza. D. N. van Gelderen.—p. 749.
143 Case of Missed Labor. L. F. Driessen.—p. 750.

138. **Cancer in Spinal Dura Mater.**—Bolten refers to primary tumors, and reports eight cases. Paresthesias and neuralgia are usually the first symptoms, but sometimes the first signs of trouble are from interruption of spinal cord functioning. In the early stages, roentgen examination is negative except when the tumor is a calcified fibroma. In only one of his eight cases was the roentgen outline distinct. At the same time, roentgen examination is very important as positive findings are so significant. Laminectomy is not particularly dangerous, and three of his patients recovered. The operation was done under local anesthesia in some of the cases. That his results were not constantly favorable was due to intercurrent pneumonia or to the general debility. These eight operative, plus two cases in which no operation was attempted, were all encountered in one year recently. One of the two patients who refused operative treatment was a man of 48 and surprising improvement followed roentgen exposures, both the violent neuralgia and the motor disturbances subsiding completely, with no return during the six months of apparently perfect health to date. Judging by other experiences, a metastatic tumor in the dura must be regarded as hopeless; they are comparatively common with ovarian and prostate tumors. Complete interruption of spinal cord functioning seldom retrogresses, even after removal of the tumor,, although he pains may have disappeared.

139. **Radiotherapy of Uterine Cancer.**—Gaarenstroom's experience with 67 cases of uterine cancer, all inoperable but 4, has confirmed the value of the combination of radium and roentgen treatment. Not that there is any essential difference between the effect of the rays on the cancer, he says, but because the anatomic and physical conditions enable one to supplement the other more effectually. His technic includes curetting, radium, 100 mg. for twenty-four hours, then roentgen exposures, vaginal, sacral and abdominal, concluding with a repetition of the radium dose, and all within four weeks, not allowing the cancer cells a chance to recuperate. Of the 58 inoperable and otherwise doomed patients, 11 have been free from appreciable manifestations of their malignant disease during the months since, from fifteen to twenty-six months in six. Great improvement was realized in 7 other cases, and 3 were improved. In only 3 of the total 58 cases was there no benefit.

140. **Radiotherapy of Superficial Cancer.**—Kuijjer reports from the same institution the experiences with superficial cancer in 63 cases. The details are tabulated for comparison, and some especially instructive cases are described in full. All were cured or improved, 24 of the 26 smaller cancers being listed as quite cured, as also 11 of the 17 large ones, 5 of the 10 very extensive ones, and 4 of the 8 lupus cancers. There has been recurrence in only 4 cases, and these were in the two first mentioned groups.

141. **Exploratory Puncture of Malignant Tumors.**—Deelman expatiates on the superior advantages of puncture over excision for differentiation of tumors. A fine needle is worked into the tumor and, as the piston is drawn up, scraping movements are made with the tip of the needle. The syringe then contains a little bloody fluid with minute scraps of tissue. It is remarkable how clear the histologic findings often are in scraps no bigger than the point of a pin. He treats them with formaldehyd, followed by acetone. This puncture can be done in the office or in the bed, and he has never had any mishaps with it or by-effects in the twelve cases in which he has applied it to date, while the findings were extremely instructive, as he shows in a plate from some of the cases.

Hospitalstidende, Copenhagen

May 15, 1918, **61**, No. 20

144 *Action of Pathologic Serum on Photochemical Processes. H. Haxthausen.—p. 609. Commenced in No. 19.—p. 578.

144. **Dermatitis from Exposure to Light.**—Haxthausen remarks that hematoporphyrin, some element in maize, and a certain kind of buckwheat are the only substances that to date have been directly incriminated in the production of certain skin affections traced to the action of sunlight, hydroa vacciniforme, etc. But there is evidence to prove that many substances under certain circumstances may have a sensitizing action on the skin. He has been studying the blood serum of patients with solar eczema or Hutchinson's prurigo restricted to the exposed portions, face, hands and forearms. The most easily studied photochemical process in the blood is the hemolysis by light, and his tests showed a much higher hemolysis index in the serum of persons with this polymorphous light dermatitis than in normal serum or in serum from other forms of dermatitis. The difference is most marked the stronger the concentration.

Hygiea, Stockholm

Sept. 30, 1918, **80**, No. 18

145 *Obstetrical Paralysis. E. Rodhe.—p. 1041.

145. **Obstetric Neuritis.**—In two of the three cases reported of traumatic puerperal neuritis and paralysis, forceps had been used. In the other case delivery proceeded spontaneously, but was long protracted. The symptoms of neuritis developed immediately after delivery in one, during the first stage of labor in one, and during the last half of the pregnancy in the third woman. The pains and paralysis in the legs subsided in the course of six weeks, three and six months. The literature on neuritis after parturition is reviewed, and the etiology discussed.

Norsk Magazin for Lægenvidenskaben, Christiania

October, 1918, **79**, No. 10

146 *Atypical Cases of Acute Leukemia. L. Dedichen.—p. 1105.
147 Cystic Ureteritis. F. Harbitz.—p. 1126.
148 Weight and Length of New Born Infants in Norway. C. L. Nielsen.—p. 1134.
149 Case of Paralysis of Brachial Plexus. S. F. Holst.—p. 1146.
150 Angina Pectoris. K. Motzfeldt.—p. 1158.

146. **Atypical Leukemia.**—Dedichen reviews the literature on atypical cases of leukemia and reports two cases which ran their course like an infectious disease with pronounced hemorrhagic tendency and gangrenous processes but no swelling of glands, although necropsy showed microscopic leukemic changes in them. There was leukopeny with lymphocytosis and severe anemia of the pernicious type. The girl of 12 and man of 35 died in less than three weeks and seven weeks after the first symptoms. Bacteria could not be cultivated from the blood during life, but streptococci and other species were found in the spleen. The third patient was a boy of 10, afebrile, no hemorrhagic tendency nor swelling of peripheral glands, but the spleen and liver were enlarged, and a lympho-sarcoma in the place of the thymus and the Mikulicz syndrome were accompanied by anemia and the blood findings of acute lymphatic leukemia. No bacteria could be cultivated from this case.

159 *Death Following Directly on Roentgen Treatment of Exophthalmic Goiter. K. Secher.—p. 1613.

154. **Influenza.**—The experiences related from Copenhagen indicate that at the same time as the epidemic of influenza—and probably a consequence of this, by the predisposition induced—a pneumococcus epidemic developed which far outshadowed the other in gravity. Sputum collected from the influenza patients immediately on entrance into any of the hospitals showed invariably numerous pneumococci, alone or predominant, whether the patient developed pneumonia later or not. Pfeiffer bacilli were not found. Similar experiences are cited from Germany. Pfeiffer himself was unable to find the influenza bacillus in a number of cases, as also Gottschlich, Schürmann and Uhlenhuth, while Kolle, Friedmann, Mandelbaum and Gruber did not find it at all. In conclusion Curschmann's report is mentioned, dated 1908, of an epidemic of "influenza" prevailing at that time in Leipzig for which the pneumococcus seemed to be exclusively responsible.

Bie and his co-workers are not positively certain that the small, distinct, regularly circumscribed colonies of diplococci were actually the *Diplococcus lanceolatus* of Fränkel. They were found constantly, gram positive, lanceolate, usually encapsulated, even when they occurred in chains. In twenty-eight cases these diplococci were cultivated pure from the sputum or droplets coughed on agar plates as soon as the patients entered the hospital, and pneumococcus septicemia developed in twenty-two of twenty-three mice injected with the sputum. The diplococci developed always either in pure cultures or as the predominating bacteria. The gross bacteriologic properties of this diplococcus and of the pneumococcus are identical, they say, but it is possible that the two may not be identical but of a closely allied species. This is suggested by the lytic drop in the temperature, which was frequently observed, as also by the occurrence of the diplococci in chains. All the links in the chains, however, were always capsule-bearing diplococci.

Scheel, in discussing what he calls the *morbus ibericus*, relates that in Norway there was quite a conflict between the physicians and pharmacists, on one hand, and the government on the other. The government had prohibited the dispensing of alcohol and strong wines, even on a physician's prescription. But the pharmacists refused to submit to this prohibition, and the government had to rescind it. Scheel adds that it is certainly doubtful whether alcohol acts as a preventive, as some believe, and owing to the prolonged course of the epidemic its use for this purpose is not to be recommended.

155. **Meningococcus Carriers.**—Hyge cites Chievitz' report that 6.8 per cent. carriers were found among 1,175 persons in the environment of meningitis patients, and 7.8 per cent. of 1,790 not known to have been in contact with cases. Only one carrier was found in 400 children; 3 among 240 civilians in a Copenhagen policlinic, and 18 per cent. among 240 soldiers in the hospital for other than respiratory affections. Thomsen and Wulff's recent compilation showed 2.1 per cent. in 474 new recruits. The meningococci may be found three or four weeks after they have apparently disappeared from the nasopharynx, but they usually vanish in about three weeks, although cases are on record of persistence for months, up to eighteen months in Kutscher's case (1912). Hyge doubts whether gargling or nose douches are effectual, advocating rather occupation out of doors and keeping away from other people as much as possible, especially during the hours of sleeping and eating, with special care as to sneezing, coughing, etc.

156. **Hysteric Spasm of Esophagus.**—The 5-year-old girl presented a grave clinical picture exactly like that with stenosis from corrosion by a caustic. Monrad commenced dilatation with a fine catheter and found that the esophagus was completely permeable. The child had actually drunk some caustic, but the first symptoms of stenosis did not appear until three months later after she had heard of a relative who had developed stenosis from such a cause. In a boy of 5 the conditions seemed to indicate a congenital diverticulum in the esophagus, but in this case also the esophagus proved to be normal on roentgenoscopy and under chloroform, although every attempt to introduce a catheter met with impassible resistance at the lower third. In this case the spasm in the esophagus had been noticed during the first year of life, the spasm occurred at different levels of the esophagus at different times, and the esophagus returned to apparently normal size and shape afterward, with no tendency to dilatation. In a third case a girl of 6 had had typical hysterical anorexia for several years, and Monrad was not surprised when the child developed the clinical picture of a diverticulum of the esophagus. A surgeon consulted counseled gastrostomy to strengthen the child for an operation on the esophagus, but Monrad found that the spasm subsided abruptly under introduction of a No. 31 catheter, after the smaller series had been constantly arrested at a point 25 cm. from the teeth. The child was apparently completely cured of all disturbances and ate with good appetite for weeks, but was brought back to the hospital a month after her dismissal presenting the same clinical picture of stenosis as before. Again it yielded to catheter treatment. In the second of the three cases, the threat of catheter treatment sufficed to arrest the spasm on several occasions.

158. **Experiences with the Wassermann Test.**—Ehlers states that in a recent series of 1,091 patients in his service at the Kommunehospital, 371 were syphilitics. In ten cases the routine Wassermann test was the only thing that gave the clue to the syphilis, confirmed by the course of the cases. He does not accept as sole testimony of syphilis a single positive response with negative responses afterward.

159. **Death Following Roentgen Treatment of Exophthalmic Goiter.**—Secher reiterates that the enlarged thyroid gland responds to roentgen treatment in very different ways in different cases. In several cases cited, an ordinary goiter seemed to become transformed into the exophthalmic type under roentgen treatment. Belot and Simon, among others, have declared that a correctly given course of roentgen treatment is free from danger, but Secher insists that this is not true. The thyroid may be whipped up to function to excess, or it may become functionally insufficient. A tendency to myxedema, however, is rare, but numerous cases of aggravation of hyperthyroidism have been reported, even with the most modern improved technic. Rieder and Verning have reported each one or two cases in which the aggravation was so intense that the patient died, and Secher now adds another case to this list of fatalities. His patient was an unmarried woman of 40, previously healthy until exophthalmic goiter developed. The thyroid was given roentgen treatment after a year, eight exposures, each ½ Saubouraud-Noiré unit, distributed in four fields, three on the thyroid and one on the thymus. Her symptoms became much aggravated at once, with restlessness, choreiform movements, pulse 100 to 200, and heart beat up to 240, respiration 72, and death the fifth day. The thyroid showed very slight changes and the thymus nothing abnormal.

IMPORTANCE OF A COMPLETE ROENTGEN STUDY OF GASTRO-INTESTINAL TRACT AND GALLBLADDER

IN ALL OBSCURE ABDOMINAL CASES *

GEORGE E. PFAHLER, M.D.
PHILADELPHIA

Generally a roentgen study of the gastro-intestinal tract is limited to the obscure cases. In such cases it is our duty to make the study complete. By a complete study, I mean the investigation of the gallbladder region for gallstones, enlargement and adhesions; a study of the stomach to prove that it is either normal or abnormal, and if abnormal, in what respect it is abnormal; a study of the duodenum; a study of the head of the pancreas; a study of the course of the food through the small bowel; a study of the appendix and the appendiceal region; a study of the colon, and very often it is advisable to make a study of the spinal column and of the urinary tract. If the spinal column and sacro-iliac region or the kidneys, ureters and bladder are to be studied, it should be done preceding the study of the gastro-intestinal tract, and should be done while the stomach and bowels are empty.

Such an extensive study involves more time and expense than an incomplete investigation, but gives a great deal more information and enables the physician or the surgeon to know the pathology and the function of these various organs so that he has a complete outline for his treatment. The expense and time consumed are increased, but one mistake will cost the physician and the patient more than ten complete examinations. Therefore, as a matter of economy as well as of efficiency, the examination should be complete. I have seen the futility of incomplete examinations so often that I almost refuse to make an incomplete study. The great majority of patients, sent to me for an examination of the "stomach" because of stomach symptoms, do not have any lesion in the stomach, but have disease of one of the other organs, most often the gallbladder or the appendix. If I were to confine my examinations to the stomach, because of the stomach symptoms, the patient would have spent time and money and would be little nearer a diagnosis than before. This is an embarrassment to the physician, a disappointment to the patient, and, to say the least, a detriment to the roentgenologist.

This does not mean that one should go through one of these abdominal studies in a routine and mechanical fashion, giving equal attention to each organ in each particular case, but, in the light of the symptoms and history, one should make an examination of all the organs, laying the greatest stress on the organ that is under suspicion, or on the organ which, during the course of the examination, suggests some pathologic condition. I have had patients who had been sent to me for gastric ulcer, and have found stone in the kidneys as the cause of the symptoms. In others, duodenal ulcer, or gallstones, or appendicitis, or intestinal stasis produced the symptoms. On the other hand, I have had patients sent for a study of the bowels because of a diarrhea and have found perforating gastric ulcer. I have had patients sent with a definite diagnosis of pyloric obstruction, probably due to carcinoma, and have found cardiospasm with enormous dilatation of the esophagus, so that the esophagus held quarts of fluid, and no lesion of the stomach. Often a patient is sent to me with suspicion of disease in the duodenum and I find gallbladder disease, or chronic appendicitis. On the other hand, symptoms of gallbladder disease are frequently due to chronic appendicitis. In some of the cases, the appendix is attached in the gallbladder region, which accounts for the peculiar location of the symptoms.

PROCEDURE

It is therefore my custom to allow at least forty-eight hours for one of these studies. I then request that the patient be given a bottle of magnesium citrate or some other agreeable purgative at 9 o'clock on the evening preceding the examination and ask him to report the following morning at 9 o'clock without breakfast, at which time, if there is any suspicion whatever of the possibility of disease in the urinary tract, a set of plates is made of the kidneys, ureters and bladder. If there is considerable aching about the spine, several plates are made of the spine. Then from six to eight plates are made of the gallbladder region. The patient is then taken into the fluoroscopic room. A hasty inspection of the chest is made with the fluoroscope, the condition of the lungs is noted, the movements of the diaphragm, the expansion of the chest, and the movements of the lung markings. The heart is studied as to size, shape, position, peristaltic movements. The mediastinum is reviewed. The abdominal cavity is inspected generally as to the curve and position of the diaphragm, and the outline of the liver and of the spleen. Very frequently one may observe the outline of the kidneys and at times detect the presence of a kidney stone preceding any opaque meal. Rarely one may even detect a stone in the gallbladder region.

I then give the patient an opaque meal, watch it pass down the esophagus, note the movements of the walls of the esophagus, the general diameter, the amount of delay at the cardia, the opening of the cardia, and the passing of food through the cardiac orifice into the stomach. I then note the rate at which the opaque material falls to the bottom of the stomach, for generally one may detect a dilated stomach merely by the characteristics of the passage of the opaque meal to the lower pole, either through gas or generally through a collection of fluid when the stomach is dilated. One may judge the tone of the stomach by the passage of the opaque meal from the upper pole into the lower pole. As the stomach fills up, one may study its size, shape, the presence or absence of filling defect, and the presence or absence of any spasmodic contraction. If spasmodic contractions are present, it is then one's duty to determine their cause, which may be either intragastric or extragastric. If no spasm is present, one searches for filling defect, and any filling defect, excepting at the pylorus, may be detected fluoroscopically. A filling defect, however, may be present at the pylorus and may be detected only after a complete series of plates is made of this particular region. I believe that valuable evidence of gastric ulcer should be detected in about nine tenths of the cases, and in the great majority of them a definite diagnosis may be made. A perforating gastric ulcer is indicated by a projection of the opaque material beyond the outline of the stomach wall.

---

* Read before the Section on Gastro-Enterology and Proctology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

The absence of a filling defect means the absence of carcinoma, and I believe a negative diagnosis of carcinoma may be made when one is certain that no filling defect is present. Yet even when a filling defect is present, one cannot always ascribe it to carcinoma, as it may be due to adhesions, or inflammatory exudate secondary to a perforating gastric ulcer, or to pressure from the outside. The actual differentiation between carcinoma and gastric ulcer is a microscopic one, and in early cases cannot be made either from the roentgenologic or macroscopic appearance, for the stage at which gastric ulcer develops into carcinoma is almost beyond recognition by the microscope. All cases having macroscopic evidence of carcinoma of the stomach should be recognized roentgenologically. Fine differentiation between indurated gastric ulcer and early carcinoma is, however, unnecessary, for such lesions should always be excised at operation and treated as if malignant.

INTENSIVE STUDY OF ORGANS

The Stomach.—The position of the stomach does not carry with it the significance that was attached to it a number of years ago. We all know now that the stomach does not have the shape nor position which was so commonly described in textbooks of ten or more years ago, and with which we, at that time, were accustomed to make our comparison of our stomach findings and to arrive at the conclusion that anything different from those anatomic illustrations was abnormal. We know now that this is not true, and that the greatest variation in the position, the outline and the shape of the stomach may be present and be entirely consistent with health and must, therefore, be considered normal. I believe that there is as much variation within normal limits with regard to the stomach in its shape and size as there is between the shape and size of various men's noses. The variation in the size and shape of a man's nose may have some significance, but it cannot be looked on as evidence of pathology. So, too, variations in the form and position of the stomach may be of some clinical significance, but can not of themselves be looked on as pathologic. The brilliant work done by Mills[1] has done much to clarify this subject, and to teach us that the size, shape and position of the stomach is very often only a matter of type, and belongs to a type of man or woman just as the size and shape of his nose belongs to his type. The size, shape and position of the stomach, however, do help us to arrive at conclusions with regard to type and our dealings with the symptoms in this type of individual may be influenced by this knowledge.

The Pylorus.—The pylorus that presents smooth gastric and duodenal surfaces is generally healthy, but even so it may be very much thickened, and this thickening may be evidence of a long-continued pyloric spasm. One may find the pyloric line of sphincter measuring approximately one-half inch in width instead of one eighth of an inch as is normal. I believe that such thickened pyloric muscle is evidence of a pathologic state, even though it may not be evidence of a local pathology. A smooth duodenal surface associated with a jagged gastric surface of the pylorus should always arouse the suspicion of carcinoma, and one should not give up until this has been proved negative. In all doubtful cases there should be a large series of small plates, or multiple exposures, taken so as to get the fixed deformities about this valve, making from twenty to forty plates or photographic exposures of this region. On the other hand, if by careful fluoroscopic examination I can clearly see the outline of the wall of the stomach and peristaltic waves moving up accurately to the pylorus, and if everywhere I find smoothness and regularity of movement, I frequently make no plates whatever of the stomach and pylorus.

The Duodenum.—This organ is studied both fluoroscopically and by plates as to its position, its outline, its peristaltic movements and filling defect, and its retention. One should recognize, I believe, at least 95 per cent. of duodenal ulcers, and this evidence is indicated by filling defect or abnormalities in the outline of the duodenum, particularly the first portion. A filling defect or an irregularity about the duodenum does not always mean duodenal ulcer, for the same defects may be caused by adhesions or even by spasms, but when spasm is present, one must always think of a duodenal abrasion or early duodenal ulcer. I am more concerned over a duodenal spasm than over a fixed indentation or niche in one of the borders. A fixed indentation of the first portion of the duodenum, together with contraction of the entire duodenum in practically all instances is due to duodenal ulcer. Like the study of the pyloric end of the stomach, any doubtful sign of disease in the neighborhood of the duodenum should be studied by a large series of plates with at least from twenty to forty exposures. These may usually be small enough to embrace only the pyloric end of the stomach and the duodenum. These plate studies of the pyloric end of the stomach and the duodenum also frequently give valuable evidence as to the gallbladder, either in demonstrating calculi or in demonstrating displacement defect due to an enlarged gallbladder.

The Gallbladder.—The study of the gallbladder should show rather definite evidence of gallstones in about 50 per cent. of the cases in which they are present, and doubtful evidence, which has some confirmatory value, in about 25 per cent. more. The demonstration of gallstones depends chiefly on the character of their composition, but also on the absolute stillness of the gallbladder, the amount of tissue overlying it, and the contents of the gallbladder. A gallbladder filled with fluid may give little or no evidence of the outline of gallstones, but one may get a general outline of it because of its increased density. This I have observed in a number of instances in connection with the strawberry gallbladder. Adhesions in the gallbladder region are indicated by abnormal attachments of the surrounding organs, such as the duodenum, the stomach, the colon, and are particularly recognizable when one is dealing with an otherwise gastroptotic stomach, in which one finds the duodenum hooked up very definitely in the gallbladder region, thus changing the entire shape of the stomach. Even the appendix may be distinctly attached to the gallbladder. One, of course, cannot observe the actual adhesions. One only recognizes the effect of the adhesions as is indicated by the displacement or fixation of the organs containing the opaque material.

---

[1] Mills: The Relation of Bodily Habitus to Visceral Form, Position, Tonus and Motility, Am. Jour. Roentgenol., 1917, 4, 155.

The Small Bowel.—As the food passes through the small bowel, one should notice any abnormal delay in any particular portion, any evidence of fixation or kinking, or excessive dilatation.

The Appendiceal and Cecal Regions.—The most favorable time to study the appendix, the cecum and the ileocecal region is at the sixth, eighth and twenty-fourth hour period, and at each of these periods one should make a careful fluoroscopic study, together with palpation by means of a wooden spoon. I prefer a wooden spoon covered with a metallic circle which will always enable me definitely to localize the point of pressure. At times, one may find the appendix filled at the end of six hours, and yet empty at each other study. The importance of seeing the appendix filled is shown by the fact that one may definitely localize its position and determine, to a certain extent, its mobility or other evidence of adhesions. Very generally the appendix is visualized at the end of eight hours, and in nearly all instances it may be seen at the end of twenty-four hours. If it is not visualized, it very commonly means that the lumen has been obliterated, or that it may be filled with exudate.

DIAGNOSTIC FEATURES OF APPENDICITIS

The important diagnostic points with reference to the appendix and chronic appendicitis are:

Localized Tenderness.—This is the most valuable sign obtained, and is elicited either by direct palpation under the screen by means of the gloved hand, or much better (which is my practice) by means of a wooden spoon-like instrument, called a "distinctor." This wooden spoon may be passed readily under the screen and is controlled by the hand above the screen over the protection of the lead glass. If this spoon is surrounded by a rim of metal, one can easily see it move around over the different parts of the colon and of the abdomen, and by watching the ring can definitely localize the tenderness of appendicitis in the cecal region or over the appendix, wherever it may be located. When the appendix is visualized (that is, when the barium meal enters the appendix so that it may be distinctly seen), one can often localize the tenderness directly over the appendix, and when the appendix is movable not infrequently the localized tenderness moves with the appendix. I have been able, in a number of cases, to move the appendix as much as three or four inches, and in each instance the sharply localized tenderness moved with the appendix. This may seem contradictory, in view of some ideas of the sensibility of the viscera, but whether contradictory or inconsistent, it is a fact. Without suggestion to the patient, I have been able to move my wooden spoon around over the abdomen, and in each instance, when I came back to the location of the appendix, the patient complained of pain, even though I had moved the appendix from its original place. This tenderness is persistent and is present throughout the various studies made. At times it is acute, and sharply localized, and at others it is more or less general and less acute. A vague tenderness is more common when the appendix is retrocecal, in which instance there is considerable soreness, but the tenderness is not sharply localized until one twists the patient in such a manner as to bring the pressure directly to bear on the appendix, in which instance the pain is often quite acute. If no tenderness is present, and if at the same time the cecum is freely movable, I believe that one may say that no appendicitis exists. If, on the other hand, there is localized tenderness over the cecum, with fixation of the cecum, and no visualization of the appendix, it very frequently means an obliteration of the appendix by inflammatory exudate, which prevents the appendix from filling with the barium meal. Localized tenderness, with fixation of the cecum, and without filling defect, I believe, is strong evidence of appendicitis. Clinically the surgeon and the physician are apt to look for tenderness over McBurney's point. As we have many opportunities of studying the position of the appendix and the localized tenderness, we realize how much in error we may be if we depend on localized tenderness over McBurney's point as evidence of chronic appendicitis. For example, if the appendix is located deep in the pelvis, there will be absolutely no tenderness over McBurney's point. Likewise, if the appendix is located in the hepatic region, and very commonly when it is retrocecal, there is no localized tenderness over McBurney's point. Then, too, the appendix may be on the left side instead of the right, either because of nonrotation of the colon or complete transposition of the viscera.

Demonstration of the Appendix.—The appendix may occasionally be demonstrated by the opaque enema, but in many more instances it is demonstrated by means of the opaque meal, particularly when administered with buttermilk. I believe that, in the majority of cases referred for gastro-intestinal study in which the barium and buttermilk meal is administered, the appendix may be demonstrated if one looks for it at the end of eight hours, at the end of twenty-four hours, and at the end of forty-eight hours. It is not always visualized in a plate made of this region, but if one palpates the cecum by means of the wooden spoon, or distinctor, if the appendix has been filled with the barium, it may always be demonstrated, I believe, even if it is lying behind the cecum. To accomplish this, one should rotate the patient to the right or to the left sufficiently to bring the posterior surface of the cecum into view. The appendix may then be demonstrated if it is filled with opaque material. I believe that no case is thoroughly studied unless this procedure is followed.

Fixation.—A chronically inflamed appendix is very apt to become more or less attached to the surrounding tissues. It may be attached only at its tip, in which instance the greater portion of the appendix could be moved around freely, together with the cecum, and yet the tip of the appendix remain in a stationary position. On the other hand, the appendix may be fixed throughout, or it may be fixed at its base, and its tip may be movable. However, absence of fixation, or evidence of adhesions about the appendix must not be regarded as negative evidence in the diagnosis of chronic appendicitis, for we all know that an appendix may be inflamed and yet be freely movable. In this instance, the localized tenderness again is of value.

Position of the Appendix.—Normally the appendix is directed downward into the pelvis, but normally it is freely movable, and changes its position without external influence to a considerable extent during twenty-four or forty-eight hours. It not only changes its position but its shape, indicating that there is likely some vermicular or peristaltic movement associated with the appendix. One may find, therefore, an appendix producing chronic appendicitis lying in a normal position in the pelvis, or lying transversely, or lying along the inner side of the ascending colon; or it may be retrocecal, or, as in one case of mine, it may be wound around the pyloric end of the stomach. In a number of instances, I have found it up in the gallbladder region, in which instances, the patients are generally sent for a gallbladder examination rather than an appendiceal study. In general, when the appendix is directed upward or is retrocecal it is more likely to indicate chronic appendicitis.

Kinking or Angulation.—The mere bending of the appendix has no significance, for its shape will vary many times within twenty-four hours, but if there is a fixed angulation it is very commonly due to an adhesion at the point of fixation. This has distinct significance.

Constriction.—Constriction, or dilatation, or irregularities in the lumen may consist of a bulbous portion, or the whole appendix may be much dilated, or one may have marked irregularity in the lumen. All these conditions, I believe, have pathologic significance.

Abnormal Retention.—If the appendix remains filled with barium after the cecum and ascending colon have become empty, or after the entire colon is emptied, I believe it has pathologic significance.

CECUM AND ASCENDING COLON

At the same time that one is making records of the appendix, one should note abnormalities of the cecum and the ascending colon, such as fixation, abnormal position, abnormal dilatation, and filling defect or abnormal retention, for one may find retention in the cecum after the remainder of the bowel has been emptied one, two or three days, and this must be recognized as an abnormal condition. One should also study the mobility of the ascending colon and its relation to the transverse colon or the surrounding tissues. If careful palpatory studies are made under the screen, one may commonly diagnose the presence of any adhesions or any evidence of a jacksonian membrane, or kinking or angulation at the hepatic flexure. The same observations may be made with regard to the remainder of the colon.

Carcinoma of the Colon.—It must be borne in mind that carcinoma of the colon may exist for a considerable period of time without giving rise to symptoms, and even after it gives rise to some symptoms many months and even years may pass before the colon is entirely obliterated or true obstructive symptoms develop. So, too, when one is making observations of the opaque meal in its passage from the mouth, one rarely finds in the early stages any appreciable localized obstruction or stoppage of the bowel. If filling defects in the bowel are seen, they must always be confirmed by means of an opaque enema, for it is my experience that the opaque meal may pass for a considerable time from above, and yet an enema be totally obstructed at the point of constriction. This must, of course, be due to some localized associated spasm. Generally, even though the constriction in the bowel is very small, an opaque enema passes through the constriction and gives a very definite and fixed deformity of the bowel which may commonly be recognized definitely as carcinoma. It is my practice to follow an opaque meal through the bowel for forty-eight hours. This gives one a fair idea as to the general function of the gastro-intestinal tract, and enables one to recognize adhesions, localized tenderness, etc., and then finally at the end of forty-eight hours, if one gives an enema and fills the entire bowel, any filling defects are noticed more definitely and positively than can be done in any other way.

The Ileocecal Valve.—The incompetence of the ileocecal valve, which is common, may be recognized very often by passing a meal from the mouth, and at times one may find the ileum entirely empty at the sixth or the eighth hour period, and yet at the end of twenty-four hours find the ileum still filled with the opaque material. This can only mean that there has been regurgitation from the bowel into the ileum, most likely due to reverse peristalsis. Patients presenting this evidence of an incompetent ileocecal valve commonly have colicky pains, often a diarrhea, and very generally a considerable amount of gas, nausea and general distress. The incompetence of the ileocecal valve, I believe, is most commonly due to intestinal stasis, and is generally associated with an atony or stretched condition of the ascending colon, and this incompetent valve is simply a part of the general stretching of the colon. At times the incompetence of this valve is due to adhesions, secondary to chronic appendicitis or to a perityphlitis. If, on the other hand, one finds no intestinal stasis present, and does find some evidence of chronic appendicitis, the presumptive evidence is that the incompetence of the ileocecal valve is due to chronic appendicitis or to a perityphlitis.

ADVANTAGES OF COMPLETE STUDY

If one makes a complete study of this kind and finds the evidence of gastric ulcer, and perhaps also the evidence of chronic appendicitis, both conditions may be dealt with at the same operation; otherwise the patient cannot be expected to get entirely well until the other abnormal condition has been rectified. So, too, if duodenal ulcer is present, and at the same time one finds a well marked intestinal stasis, one cannot expect complete recovery until the intestinal stasis is also dealt with, as well as the duodenal ulcer. In fact, at times the symptoms of the duodenal ulcer will disappear if the intestinal stasis is thoroughly and competently treated. With reference to the gallbladder, I have seen patients that have traveled all over this country consulting the best stomach specialists because of severe and persistent stomach symptoms, and only stomach symptoms. Yet I have found in them gallstones, the removal of which relieved all gastric symptoms. I have found gallstones by roentgen-ray examination because I had made a complete study, when all the symptoms seem to point toward a urinary rather than a biliary colic, even to the extent that the patient passed a slight amount of microscopic blood in the urine.

Chronic appendicitis, I believe, gives rise to more obscure symptoms in the abdomen than any other condition, and yet gives the most elusive evidence on which to base a diagnosis. If one makes a complete study of the alimentary canal, together with the gallbladder, and at times the urinary tract, spinal column and sacro-iliac region, one can practically always make a diagnosis or find pathology sufficient to account for the abdominal symptoms. I believe that such a complete study thoroughly done by a competent, skilled roentgenologist is of as much, and at times more value than an exploratory abdominal operation. Within a short period of two weeks, there have been sent to me three patients who have had exploratory operations done by competent surgeons because of the symptoms of gastric ulcer, in whom no evidence of gastric ulcer could be palpated by the surgeon, and the abdomen was closed. Within a year these patients were sent to me and in each of these three patients I found the evidence of malignant disease which was confirmed by a subsequent operation.

If such a complete study of the abdomen is made, I believe that carcinoma, if not present, can be eliminated from consideration in the diagnosis, and if present can, I believe, in all instances be diagnosed, or at least pathology suggesting carcinoma will be recognized which will be sufficient for an operation. The exploratory operation will then be for a definite purpose, at a definite location, to investigate a definite lesion, and when roentgen evidence points to carcinoma in the gastro-intestinal tract, the surgeon should be very sure that it is not carcinoma before he ridicules this diagnosis or eliminates it from his consideration.

CONCLUSIONS

1. A complete roentgen study should be made in all obscure abdominal cases.
2. Such a study should determine each organ to be either normal or abnormal, and if abnormal, the nature of this abnormality should be carefully described.
3. The diagnosis of carcinoma, if present, may practically always be made.
4. The absence of carcinoma may, in most instances, be proved.
5. Gastric ulcer may be recognized in about 90 per cent. of the cases.
6. Duodenal ulcer may be recognized in probably 95 per cent. of the cases.
7. Gallstones may be recognized in approximately 50 per cent. Other evidence of gallbladder disease may be obtained in 25 per cent. more.
8. Chronic appendicitis may be diagnosed in practically all instances.
9. Incompetence of the ileocecal valve may be recognized, and diagnosed only by this procedure.
10. Defects, adhesions, filling defect and abnormal function of the bowel may be recognized by this method better at times than by operation.
11. Diverticulitis may be recognized only by this method and by operation.
12. Carcinoma of the rectum may, at times, be more definitely determined as to its position, location and its extent than by a proctoscopic examination.
13. Patients generally obtain a great deal of mental satisfaction that is helpful in the cure of their cases, as the result of a complete study of this kind.

ABSTRACT OF DISCUSSION

DR. BERTRAM W. SIPPY, Chicago: Dr. Pfahler has presented the subject from the standpoint of the roentgenologist. It appeals to two classes, those who, through experience, have been conducting roentgen-ray examinations of the gastro-intestinal tract for diagnosis, and those who are familiar with it only through writings and hearsay. Our duty is not done in obscure cases until we have made a complete examination. The difficuty is, how do we know that a case is obscure? Sometimes it may appear to be obscure when it is not; and mistakes in diagnosis are apt to be made by making only a routine examination. If we are going to diagnose cases properly, we may well refer them to a competent roentgenologist.

The doctor made a very strong plea for complete examination. I wish to supplement that plea by making a plea for complete examination nonroentgenologically. Physicians usually are too narrow in their vision of intestinal troubles, looking at intestinal troubles only with the idea of giving cathartics or enemas. They are confused by intestinal stasis, by disturbance of the ileocecal valve, by Jackson's membrane, by a large amount of rubbish, names that have very little significance. They should know these things are remedial, and that there are not very many diseases or disorders of the stomach for which patients seek relief. If we eliminate cathartics and enemas and rivet attention on the serious possibilities, realizing that by working with a little understanding, there are mighty few cases that cannot be studied without roentgenology and conclusions drawn that will be influenced very little by roentgenology. Having started this work before we had the roentgen ray to help us, we developed a certain technic in our diagnosis of gastro-intestinal disorders, and we make fewer mistakes when we carry that out as accurately as possible than we would otherwise. When one does that, I want to say to you, from long experience, that it is possible to do your work so accurately that it is only now and then that the roentgen ray will give you very material advantage. But we cannot get along without it, because we do not know just what it is going to show. It will show things like these diaphragm hernias that you cannot get in any other way.

DR. WILLIAM VAN VALZAH HAYES, New York: I am disposed to endorse strongly every word Dr. Pfahler said, except one statement, that the only way we can tell if the ileocecal valve is incompetent is by means of the roentgen ray. I do think we can frequently get information about this if we use our hands and ears intelligently.

I wish to emphasize what Dr. Sippy said of the extreme importance of a thorough study of the case by the gastro-enterologist before the roentgenogram is made. I do not think that giving the barium meal, and seeing if the stomach is empty in six hours, is an adequate test of the duration of digestion. The stomach may act differently with different meals, and it is very desirable to make other tests, such as the rice and raisin test and the "duration" test (two soft-boiled eggs, a glass of water and roll), which should be out of the stomach in three and a half hours. The roentgen ray furnishes extremely valuable confirmatory evidence, and sometimes gives an insight into conditions that would be overlooked without it. For example, we have gone over the abdomen carefully, and have concluded that the organs are all in normal position; we have tested the position of the stomach with the patient reclining and have found the greater curvature at the umbilicus, or slightly below, and all seems to be right in that respect. We send the patient to the roentgenologist, and learn of the existence of a very marked gastroptosis. It has been shown that when the patient stood with the meal in the stomach, the stomach dropped down about 4 inches. Some of these patients can be relieved by using a supporting belt or corset. The roentgen ray is particularly valuable in showing the presence or absence of filling defects in the stomach and bowel, and this, perhaps, constitutes its most important aid in gastro-enterologic diagnosis. We should avail ourselves of the skill of the roentgenologist to the greatest practical extent, in order to get a full-rounded diagnosis. If we do, and if we make thorough studies ourselves, we can go forward in confidence, feeling sure we shall know whether there should be an operation or whether we can get results by medical treatment.

Dr. A. Heinen, Chicago: The view of the gentlemen preceding me as to the value of roentgenology in gastro-intestinal disturbances is correct. I always contend that if you depend on the diagnosis of gastro-intestinal disturbance by the roentgenologist, you will make more mistakes than you ever made. The principle in diagnosis of gastro-intestinal disturbance is a thorough physical study of the case and the laboratory findings. In the diagnosis of ulcer of the stomach by the roentgen ray, retention may be due to spasm; but as we are all most concerned by the importance of the diagnosis of carcinoma of the stomach—which means death to the patient—I think that an early diagnosis of carcinoma is of the greatest importance, because you can save the patient's life by the proper surgical procedure. The roentgen ray fails in the early diagnosis. The early diagnosis of carcinoma is made only if you seek for carcinoma. If the roentgen ray shows that carcinoma is there, it is a late diagnosis. In the early diagnosis of carcinoma, I rely on the history, physical examination, and, above all, on the occult blood test of the stool. Carcinoma of the stomach is mostly the medullary form and begins in the mucous membrane; it consists mostly of blood vessels—very little stroma—and as the growth breaks down constantly, blood always is present in the stool. If you find occult blood in the stools for a period of a week, carcinoma is present. The roentgen ray will not show anything in this stage, not until two or three months later, when the patient is doomed.

Dr. J. Guttman, New York: We can all fail once in a while, particularly if we base the diagnosis on one fact. Dr. Pfahler did not intend to convey the impression that we should limit our diagnosis to roentgen ray. He intended to say that it is absolutely necessary to be thorough, whether you do it in a clinical way, or in a chemical way, and when you do it from the roentgenologist standpoint you must be particularly careful to be thorough, because it is the little details which enable you to make a correct diagnosis. Why is the diagnosis more important than anything else. No physician has done his duty to his patient, in spite of any effective treatment he may have instituted in that particular case, unless he knew why he was making the application of this particular therapy. So first and foremost comes the diagnosis. If we can make a diagnosis without the aid of any tests, well and good, but if not, let him resort to chemistry and the roentgen ray. If I were to chose my methods of diagnosis, I would say, give me clinical experience; if my clinical experience teaches me that I am dealing with a gastric ulcer, and the laboratory findings may tell me there is achylia gastrica and other evidences present which might indicate carcinoma, I shall be firm in my diagnosis of gastric ulcer. If clinical experience tells me I am dealing with carcinoma of the stomach, and the roentgen ray will fail to find definite or other evidence, I shall still put my faith in my clinical diagnosis. Often the roentgen ray leads in the proper direction, not always; but the failures are not so much because of the ray itself, but because of the way it has been used. It depends entirely on the man and on the method used, and on the interpretation of the findings. But taking it as a whole, first comes proper clinical diagnosis, then the laboratory work, whether it is chemical or roentgen ray, done in the proper way and by an expert. The time is coming when we will all become expert in roentgen-ray laboratory work, when every man who is considered a gastro-enterologist will not make a diagnosis unless he is a roentgenologist. It is going to be a necessary part, just as much as knowing how to handle a stomach tube. Dr. Pfahler says he finds the appendix very often. I never saw the appendix visualized as frequently in giving the patient the ordinary barium meal or carbohydrate meal as I do when I give him buttermilk. After twelve or fourteen hours, I find the appendix visualized, if it can be visualized.

Dr. Horace W. Soper, St. Louis: Boas, who originated the occult blood test, has always admitted that it was of no value in the early diagnosis of cancer. He states so explicitly, and I think that this has been the general opinion of all men of large experience with the test. It occurs late in the development of the growth. No examination of the gastro-intestinal tract is complete without the roentgen-ray findings; and in the hands of an expert it is our only method of obtaining an early diagnosis in cancer. I think that Dr. Pfahler's percentage figures in relation to ulcer and appendicitis are very conservative.

Dr. George E. Pfahler, Philadelphia: More mistakes in diagnosis are made through carelessness than through ignorance; and that applies whether it be in roentgenology or any other method of diagnosis. It is lack of thoroughness that is generally the cause of the mistakes. The mistakes in the diagnosis of carcinoma of the rectum in the majority of instances are due to the lack of the physician putting his finger into the rectum. The great majority of cases that have gone on for a long time have been neglected because the physician has not introduced his finger into the rectum; and that is only an illustration of the absolute carelessness that is going on all over the country in the matter of diagnosis, and it applies to clinical medicine, and perhaps even more to roentgenology. In regard to the ordinary clinical examination—and the roentgenologic findings are also clinical—I agree with everything Dr. Sippy said, and everything Dr. Hayes said. Of course, we should use every means of diagnosis, and use the roentgen ray also, and you will have that much more thoroughness in the diagnosis. When the diagnosis differs, there is something wrong in the observations some place, and it should be corrected by more thorough study.

With regard to the diagnosis of early carcinoma, I challenge not only Dr. Heinen, but any man, to make a diagnosis of carcinoma—the early diagnosis of cancer of the stomach that I cannot make with the roentgen ray, if the work is done thoroughly. You cannot, however, make such a diagnosis if you are going to depend on technicians, men who are simply paid to work a certain time, and are generally underpaid. In certain cities some hospitals have no physicians in charge of their roentgen-ray department. They depend on the technicians to make their studies, and then commercialize the roentgen-ray department so that they can get the greatest amount of money for the least amount of work out of them. That is the cause of mistakes in diagnosis, and that is what prompted me to write this paper. Patients are sent for a stomach examination at so much per, and then because a mistake is made he comes back and damns the roentgen ray. The patient thinks he has had a roentgen ray examination, but you know he has not. The patient is the one who suffers. Somebody gets some coin that does not belong to them. The only plea I make is, more thoroughness in the roentgen-ray examinations and thoroughness in the clinical diagnosis.

Epidemic Diseases in City and Country.—It is true that epidemics of disease spread with greater rapidity in the cities owing to the fact that the infected person is liable to come in contact with a large number of persons in a short time. But sources of infection are more promptly located, the hospital for contagious diseases is made use of without delay, and the common agencies for the prevention of disease in our cities are not so readily available in the sparsely populated parts of the state. By this I refer to the efficient health organization of the city with its corps of inspectors, laboratory workers, epidemiologists, etc. Added to this is the efficient nursing organization, ever ready to lend timely aid.—Byron U. Richards, M.D., *Bulletin Rhode Island State Board of Health.*

THE DIAGNOSTIC AND PROGNOSTIC VALUE OF BLOOD UREA IN UROLOGY [*]

ALBERT E. GOLDSTEIN, M.D.
Associate in Genito-Urinary Surgery, University of Maryland School of Medicine and College of Physicians and Surgeons; Attending Urologist to Hebrew Hospital
BALTIMORE

In partially reviewing the literature on urology of the past three decades, one's attention is immediately attracted to the advances made on the surgical and diagnostic sides, though the advances of the former depend almost entirely on the latter. That is, as the newer methods in diagnosis of urologic conditions have developed, the urologist has become more competent as a prognostician and therefore was enabled to perform operations that otherwise would not seem feasible. Furthermore, the advances in diagnosis have been principally aided by the more modern laboratory methods of the blood and urine, and one finds himself dependent on the various chemical tests of the blood and urine, together with the action of various dyes on certain organs before a urologic operation is performed.

The work of Koranyi[1] on cryoscopy, of Heidenhain[2] on indigocarmin, of Von Mering[3] with the phlorizin test, of Geraghty and Rountree[4] on phenolsulphonephthalein, and the various contributions to science on the methylene blue test, rosaline test, indigocarmin urine urea and other examinations of urine, etc., are doubtless familiar to all the members of this Association.

The literature up to date is teeming with endless variations of these tests, each having its own followers, each one in itself being applied best to certain classes of cases only, and each one an excretory test. In most institutions, three, four or all the tests were employed, and from the data collected from the combination, conclusions were drawn. In view of the misleading interpretations that followed the use of some of the foregoing methods at various times and in various classes of cases, the importance of retention tests was soon recognized, and in the past few years less stress has been laid on excretory tests and much more stress on some of the retention tests, particularly blood urea, nonprotein nitrogen, creatin and uric acid.

The work by Marshall and Davis[5] on "The Distribution of Urea and its Elimination from the Body," the work by McClean and Sellig[6] on "Urea and Total Nonprotein Nitrogen in Normal Individuals," and that by Folin and Denis[7] on "The Diagnostic Value of Uric Acid Determinations in Blood," have encouraged investigators to seek methods from which more conclusive data could be obtained than by the excretory methods which at all times and in all classes of cases did not correspond. Schwartz and McGill,[8] in their series of 211 cases, have shown conclusively the importance of blood urea, and Tileston and Comfort[9] have demonstrated the relationship of it in health and disease. Gillard[10] employs it with great satisfaction in the diagnosis of surgical diseases of the urinary tract and Scherck and Gradwohl[11] have shown conclusively that no urologic case is completely examined for diagnosis or operation without the employment of a retention test.

My investigations for the past three years have been carried out practically along the same lines as those of Scherck and Gradwohl, the principal retention test employed being that of blood urea. The cases selected for the work were all urologic cases, in the services of Dr. Rytina and myself.

The method employed for determining the blood urea at first was Marshall's[12] (that of using serum), and later Van Slyke's[13] (that of using whole blood) and calculating on the per liter of blood basis with a normal consideration of from 0.3 to 0.6 gm. per liter of blood. The number of cases in my investigations up to the time of writing was 104, on which 280 blood urea determinations were completed.

For purposes of comparison and to demonstrate partially some of the surpassing qualities of blood urea in relation to diagnosis and prognosis in genito-urinary surgery, I have employed the three following tests, which are the most uniformly used and the simplest of application: (1) the urine urea test; (2) the phenolsulphonephthalein test, and (3) the ordinary chemical and microscopic examinations of urine (albumin, casts, etc.).

METHOD OF PROCEDURE

The method of procedure was as follows: When a urologic case was admitted to the hospital, some urine was taken for microscopic and chemical examination. An intravenous injection of phenolsulphonephthalein was given, some blood was taken for a blood urea and whenever possible, a twenty-four hour specimen of urine collected for urine urea determination, either the Hüfner[14] or Marshall[15] method being employed. The patient was not placed on any special diet, except in cases in which possibly there were some constitutional disturbances present. Therefore the intake of proteins was practically constant and did not interfere materially with the relative comparisons of the blood urea, although the patient was advised to drink water copiously. In from three to five days, the same procedure was carried out to determine the course of the case, that is, whether conditions were becoming more or less favorable for the patient and for the surgeon. If the various tests, particularly the blood urea, were within normal limits on the first examination, and the second examination demonstrated an improvement or lack of improvement, I could at this time begin to consider the prognosis of the case, should operation be contemplated. If the blood urea increased in amount, which of course indicated a higher degree of toxicity, operation was delayed and the blood was taken again in from three to five days. This procedure continued until the blood urea reached within the normal limits of from 0.3 to 0.6 gm. urea per liter of blood. In most cases a phenolsulphonephthalein was given at the same time that the blood was taken for urea determination. Should the blood urea, after a number of determinations, not reach the upper normal limits, then when a stationary point was reached and the operation was imperative, it was performed, providing the stationary point was not too far above the upper normal limits. In this manner, I was able from my series of cases to standardize approximately (as one might call it) the minimum and maximum retention of urea that might be present in the blood before operation was performed with impunity. This will become apparent from the study of the accompanying tables. Here it is obviously seen that only rarely did a patient recover from an operation with a blood urea of more than 1 gm. per liter of blood (the prognosis being considered grave here at all times) and at no time was the prognosis grave, urologically speaking, with a blood urea of less than 0.75 gm. As will become apparent from the study of the accompanying tables, in the few cases in which the patients with blood higher than 1 gm. were operated on, it will be readily observed that the patients developed uremia, the prognosis having been made before operation. This development took place in all cases with the exception of certain types, such as some prostatic hypertrophies and strictures of the urethra, in which a cystostomy was imperative for retention, irrespective of the condition of the patient. Then the operation was subsequently completed if conditions permitted, as in Cases 24, 31 and 55, all of which were stricture cases with recoveries following operation. Peculiar as it may seem, patients with a blood urea of more than 1 gm. who were operated on and recovered, appeared not to have as stormy a recovery if the obstruction were a urethral, rather than a renal or prostatic obstruction. Whether this is a mere coincidence or the resisting powers are greater, I am unable to state.

---

In cases with a blood urea between 0.75 and 1 gm., in which operation was necessary, only a fair prognosis was made, depending on whether the stationary point reached was a progressive decrease or a progressive increase in the amount of blood urea. This point was determined only by a series of blood urea determinations, best demonstrated in Case 86. This patient is at present in the hospital and has been there for the past three months under the preoperative regimen. His blood urea on admission was 0.55 gm. urea with a phenolsulphonephthalein of 55 per cent., and 10 gm. urine urea daily. Blood urea tests were completed in from five to seven days, with a result that there was a constant variation rising to 0.81 and dropping back to 0.6 and then rising again. In view of other conditions present, this patient would be a surgical risk, unless his blood urea would remain stationary, somewhere below 0.75 gm. or between 0.75 and 1 gm. A point of great interest here is that the blood urea and phenolsulphonephthalein were within normal limits on admission and, should dependence have been placed entirely on the one determination, this patient would unquestionably have developed uremia and died. Hence the importance of a series of blood urea determinations before operation. In only one case in which the patient was operated on and in which a very favorable urologic prognosis was given before the operation, the patient died from a renal insufficiency, that is to say, of a uremia following an acute renal suppression probably due to the

TABLE 1.—COMPARISON OF RESULTS OF BLOOD UREA, PHENOLSULPHONEPHTHALEIN AND URINE UREA TESTS

Case Number	Name	Diagnosis	Blood Urea Gm. per Liter of Blood				Intravenous Phenolsulphonephthalein for Two Half-Hour Collections			Urine Urea Gm. per Diem, Doremus			Urine Examination	Prognosis		Operation	Results	Remarks

* None obtained. † Unable to obtain on account of perforating fistula.

administration of ether or some other unknown cause, as no necropsy was obtained.

CASE 1.—The case is worthy of mention. The patient was H. A., a man, aged 60, with a diagnosis of papilloma of the bladder and a moderate benign hypertrophied prostate. His blood urea on admission and previous to operation was 0.33 gm. per liter of blood, the phenolsulphonephthalein test was 45 per cent. for two half hours. The urine examination showed many red and white blood cells. Cystoscopic examination revealed a small papilloma of the bladder and slight intravesical bulging of the prostate. The systolic blood pressure was 145, the diastolic 95, and the heart and lungs normal. In view of the excellent condition of the patient, he was operated on three days after admission. The papilloma with the normal surrounding tissue was excised and a sphincterotomy performed at vesical neck. Two days after operation the patient had the appearance of being toxic, drained only about 250 c.c. in more than twenty-four hours, in spite of forced liquids, infusions, etc., and before blood was taken for a blood urea test the patient died, three days after operation. We were unable to obtain necropsy, but with a preoperative normal blood urea and a suppression following operation, the cause of death seemed *obvious*. I regret very much that I did not have a blood urea test in this case, previous to the patient's death.

TABLE 2.—RELATION OF BLOOD UREA TO URINE ANALYSIS IN OPERATIVE CASES

Case Number	Name	Diagnosis	Blood Urea Gm. per Liter of *Blood*				Intravenous Phenolsulphonephthalein for Two *Half-Hour* Collections			Urine Urea Gm. per Diem, *Doremus*			Urine Examination	Prognosis on Admission	Operation
			Admission	Preoper. 1st	Preoper. 2d	Postoper.	Admission	Preoper.	Postoper.	Admission	Preoper.	Postoper.			
12	D. B.	Benign prostatic hypertrophy	1.7	...	...	...	Trace	....	....	..	..	..	Albumin —, red blood cells —, white blood cells —, *organisms* +	Grave	None
16	T. L.	Benign prostatic hypertrophy	0.78	0.45	0 45	0.41	35%	55%	....	20	..	..	Albumin +, few pus cells	Good	Perineal prostatectomy

5	A. E.	Malignant prostatic hypertrophy	2.6	3.4	...	...	None	None	....	..	..	..	Albumin —, white blood cells or red blood cells, specific gravity 1 002	Grave	No operation
37	M. M.	Benign prostatic hypertrophy	0.68	0.64	...	0.5	*57%*	58%	60%	..	..	..	*Albumin* +. few white blood cells	*Good*	*Suprapubic* prostatectomy
40	B. R.	Benign prostatic hypertrophy	0.6	0.6	...	...	55%	54%	....	18	..	..	Few white blood cells	Good	Suprapubic prostatectomy

Seven other patients that were operated on died after a favorable prognosis was given based on the blood urea determination, but here in all the cases the cause of death was not a renal insufficiency, as will be apparent from the study of the accompanying cases. One died of a pulmonary edema following a perineal prostatectomy, a second of a streptococcus infection following a cystostomy for drainage, a third of a septicemia following a suprapubic prostatectomy, and a fourth of starvation, in which case the patient was of the demented type and, following operation, refused nourishment. A fifth died of pneumonia following a suprapubic cystostomy, a sixth died of pneumonic tuberculosis following a nephrectomy, and a seventh died of pulmonary embolism following a nephrectomy. Certainly a urologist cannot be blamed for the deaths of the foregoing seven patients, as these deaths could have occurred in any other operative cases.

ADVANTAGES OF BLOOD UREA OVER URINE UREA TEST

The advantages of blood urea over urine urea *will* become apparent from the study of Table 1, the principal advantages being as follows:

1. The great variation, which exists in the normal and leads to inaccurate interpretations, on which account it is difficult to determine when one is dealing with a borderline case.
2. The disappointing results produced by the quantitative estimate of this normal urinary constituent, because of the fact that the amount of these substances excreted depends not only on the functional activity of the kidney, but on the amount of these substances carried to the kidney for excretion.
3. The inability to obtain a correct and fairly accurate twenty-four hour specimen of urine.

From a study of a series of tables I have completed, of which only three have been included in this paper for lack of space, it was observed that from the urine urea determinations certain patients would have been considered favorable surgical risks and others unfavorable surgical risks, best demonstrated in some of the cases of the accompanying tables.

CASE 2.—The patient whose case was of particular interest from this standpoint was B. C., a young man, aged *24*, who developed a lobar pneumonia. During his convalescence, a partial suppression of urine set in, and the first four days after I saw him, he voided between *175* c.c. and *300* c.c. of urine in twenty four hours. His blood urea *during* these four days *remained* stationary, that is, from 1.44 to 1.45 gm. per liter of blood. A very grave prognosis was given. An intravenous phenolsulphonephthalein in this case showed only a trace of phenolsulphonephthalein for two, one-half hour collections. His urine urea remained fairly constant during these days, varying from 1.05 to 1.36 gm. per diem. There were albumin, casts, and red blood cells constantly in the urine with a specific gravity ranging from 1.008 to 1.014. Under forced fluid intake, on the fifth day, he excreted 1,250 c.c. of urine with a specific gravity of 1.010, a urine urea of 12.4 gm., and a blood urea of 2 gm. In spite of his increased urine urea, his blood urea increased. *I* gave a very unfavorable prognosis. On the sixth day, his output increased to 3,500 c.c. with a specific gravity of 1.012, a urine urea of 35 gm., a phenolsulphonephthalein of 3 per cent., but a blood urea of 2.7 gm. On the seventh day, the urine urea increased to 38 gm., and the blood urea to 3.2 gm. In spite of the increase in the output of urine and the increase in urine urea, after his blood urea left the stationary point of 1.45 gm., the outcome of the case to me was obvious, and on the eighth day, with an output of 4,000 c.c. of urine with a specific gravity of 1.012, a urine urea of 40 gm. and a blood urea of 3.2 gm., the patient died of a toxic uremia and pyemia. During the last three days, his temperature ran very high with a high leukocyte count, and he had areas of tenderness in several parts of the body.

The discussion of this case is simple. Under the forced intake of fluids, the kidneys began excreting hypernormally, conveying with the excretion only a small quantity of solids; hence the low specific gravity. The liver in this case was unquestionably manufacturing an extra quantity of urea (Van Slyke[16]), which was being partially taken up by the kidney and excreted in the urine; hence the high urine urea. But with the increase in the manufacture of urea by the liver, the kidneys were excreting only part of it and the remainder of it was being stored up in the circulation; hence the increase in the blood urea and toxic condition of the patient. This is one of the types of uremia cases that I believe Foster[17] classifies.

DIFFICULTIES OF PHENOLSULPHONEPHTHALEIN TEST

Every urologist, I am certain, has met with certain types of urologic conditions in which, on account of mechanical impossibilities, it was difficult for phenolsulphonephthalein to give a true status of conditions. This will become apparent from the study of Table 1. Here it is again observed that Cases 24, 25 and 31, from a standpoint of the phenolsulphonephthalein test, would have been poor operative risks, but from the blood urea determinations, operation was deemed advisable and the patients made uneventful recoveries. Vice versa, some cases had high or apparently normal phenolsulphonephthalein, but high blood ureas, and in each case the patient died before operation was undertaken. Fortunately, this has not occurred many times. In this manner many cases have been diagnosed as good operative risks and others diagnosed as poor operative risks, according to the blood urea examinations. When renal surgery is necessary, blood urea in itself is not sufficient. Here it may be employed only as a prognostic agent. For diagnosis, it is absolutely essential to obtain relative renal function, and it is here that I believe the excretory tests, such as phenolsulphonephthalein, indigocarmin and urine area, are indispensable.

TABLE 3.—BLOOD UREAS IN TWO-STAGE PROSTATECTOMIES

* Unable to obtain.

The presence or absence of albumin, pus and casts today does not play as important a rôle as it has in the past excepting where a renal or vesical lesion is suspected, and here it is ruled out by cystoscopy and catheterization of ureters, which is very essential. But for the presence of abnormal constituents in patients to be operated on for the prostate urethra, or bladder, I am certain that if other conditions are within normal limits, operation need not necessarily be delayed.

Other tables were completed, but are not to be presented in this paper for lack of space in which the blood urea phenolsulphonephthalein and urine urea practically all agreed, and from which sufficient data could be collected from the combination, enabling the urologist to proceed with the necessary operation with safety. This last class I may say, though, did not include more than 60 per cent. of the cases. In the other 40 per cent. of the cases there were disagreements in results of the tests, so that if phenolsulphonephthalein and urine urea had been depended on entirely, operation would have been performed, and our mortality rate would have been increased, as in most instances the patients developed uremia and died.

[17] Foster, N. B.: Uremia, The Journal A. M. A., Sept. 23, 1916, p. 927.

As a prognostic agent in genito-urinary surgery, I consider blood urea to be almost infallible, and from my results deduced in my many investigations, I can readily say that a favorable or unfavorable prognosis may be made, according to the amount of blood urea present at various times, only to be determined by the studying of a series of urea tests of the blood in each case.

TYPES OF OBSTRUCTIONS

In the series of 104 cases, there were eighty patients operated on and twenty-four not operated on. This included all the genito-urinary conditions, but the variations that existed were principally in the following classes of cases: (1) certain types of hypertrophied prostate; (2) large vesical calculi; (3) impassable strictures of the urethra; (4) stones in the ureter; (5) pyelitis; (6) suppression of urine; (7) large vesical neoplasms; (8) strictures of the vesical neck; (9) diverticula of the bladder, and (10) uremia.

A brief survey of the surgical pathology of each of the foregoing conditions will convince the reader that he is dealing with a mechanical obstruction in most cases. Therefore, there should exist a difference between the excretory and the retention tests, accuracy being detailed to the retention test, principally for the reason that the entire excretory function, be it phenolsulphonephthalein or urine, cannot be collected entirely through the medium of voiding or catheterization. In some cases, this is true of hypertrophied prostates, when some urine is retained in the bladder that the catheter does not remove, principally when there is a large median lobe, therefore the calculation is inaccurate; hence the reason for the wide discrepancy between this and the retention test. In large vesical calculi, large vesical neoplasms, and in some cases of diverticula of the bladder, the same condition exists; not all the urine can be collected, therefore, all the phenolsulphonephthalein is not collected. Here is a case of particular interest:

Case 3.—H. W., aged 54, was admitted to the Mercy Hospital from a neurologic sanatorium to have a perineal prostatectomy done. The urethra of the patient was very sensitive, and in addition to his being demented, he refused a complete examination, allowing only a rectal examination. A large hard mass was felt which at the time was considered to be prostatic tissue. The urine examination revealed a normal specific gravity, a low twenty-four hour urine urea, a phenolsulphonephthalein test of only 5 per cent. for two half hour collections and a blood urea of 0.5 gm. In spite of the low phenolsulphonephthalein, a perineal prostatectomy was decided on. In fact the patient insisted on an operation through the perineal route. After the patient was anesthetized and a sound passed into the bladder, a definite click of a calculus was obtained. The urethra was opened through the perineum, the finger was inserted into the bladder, and a very large calculus was felt. On account of its large size, it could not be delivered through the urethra, and a suprapubic cystotomy was necessary. A stone weighing 9 ounces was removed. The patient did nicely for several days after the operation, but beginning on the fifth day following the operation, he refused to take nourishment. We forced feeding through tubes both rectally and by mouth, but in spite of all this, he died on the twelfth day following operation. His blood urea before death was 0.5 gm., the same as before the operation. There is practically no discussion to this case, excepting that the phenolsulphonephthalein was low, due to the inability to collect all the urine which contained the phenolsulphonephthalein and not because it was not excreted.

In the cases of impassable strictures of the urethra and strictures of the vesical neck, here again all the urine is not voided or collected through a catheter, and again the phenolsulphonephthalein reading becomes inaccurate from the standpoint of dependability. In all the foregoing types of cases that I have mentioned, the phenolsulphonephthalein, probably in a large number of cases, was excreted, but not collected, the fault lying not in the excretion of the drug, but in the collection of it on account of the obstruction. Likewise, in the case of stones in the ureter, the kidney on the involved side is excreting the phenolsulphonephthalein, but on account of the obstruction all the urine is not passing by the calculus; hence inaccurate results again. In the cases of pyelitis, a different picture presents itself. Invariably, if not in all cases of pyelitis, we have an accompanying dilated pelvis which may have a capacity of from 10 to 200 c.c. Here again, if there has not been total destruction of the kidney, the urine or dyes, whatever they may be, are being excreted, but unless a ureteral catheter is inserted to withdraw the retained urine in the pelvis, accuracy cannot be obtained. This is best conveyed to the mind of the reader by the following case:

Case 4 (No. 63).—B. C., aged 24, was admitted to Mercy Hospital with a complaint of urinary frequency. The urine examination revealed a very large quantity of albumin, pus cells, a few red blood cells, colon bacilli and staphylococci; a combined phenolsulphonephthalein of 26 per cent. was obtained for two half hour collections. The patient was cystoscoped, her ureters were catheterized, and many pus cells, colon bacilli and staphylococci were obtained from both sides. The pelvic capacity of each kidney was between 75 and 80 c.c. Both kidneys functioned with a continuous drop suggesting a hydronephrosis. The blood urea at this time was 0.6 gm. per liter of blood. The diagnosis of bilateral pyelitis of pregnancy was made. The pelvis of each kidney was irrigated with a 1 per cent. solution of silver nitrate. This procedure was carried out once a week for six treatments, and at the end of this time, the patient felt very much improved. A relative phenolsulphonephthalein test was obtained giving 35 per cent. output from the right kidney and 11 per cent. output from the left kidney, a total of 46 per cent. The blood urea at this time was 0.37 gm., showing a marked improvement. She left the hospital, returning for treatments. Two months later the patient was admitted to the hospital to be delivered. A combined phenolsulphonephthalein test gave only 21 per cent output. A blood urea at this time was 0.48 gm. per liter. One week later the patient was delivered and made an uneventful recovery.

In discussing this case, it is obvious that with existing bilateral hydronephrosis, some of the urine was retained in the pelvis of each kidney, this being demonstrated at the time of each pelvic lavage. Keeping this point in mind together with the fact that when a relative phenolsulphonephthalein was given and collected by catheterization of the ureters, we find that an output of 46 per cent. was obtained. At the time of the patient's delivery her blood urea as stated was 0.48 gm., which is within normal limits, while her phenolsulphonephthalein was only 21 per cent., which is below the normal. This is undoubtedly due to the retention of phenolsulphonephthalein in the pelvis of each kidney, as a previous phenolsulphonephthalein of 46 per cent. was obtained after its injection and collection by catheterization of the ureters. On both occasions, the blood urea was well within the normal limits.

The blood picture in all cases of pyelitis varies from the information obtained from phenolsulphonephthalein. The dye or urine for the hour or two of calculation is being excreted by the kidneys according to the extent of the lesion, but is partly retained in the pelvis of the kidney. The decrease of the output of phenolsulphonephthalein in these cases always exceeds in proportion the increase in the retention of urea. The only explanation that can be offered here is the theory of retention in the pelvis. In suppression of urine and its subsequent condition of uremia, we have two conditions which may be recognized sooner by a series of blood urea determinations than by any other test, simply on account of its being a retention test. On several occasions, an oncoming uremia was diagnosed in this way long before the information was obtained by the excretory tests.

As the cause of death in a large percentage of patients operated on for urologic condition is uremia, it is of utmost importance to the urologist and surgeon to diagnose this condition before the operation, thereby lowering materially his percentage of mortality; and it is here that blood urea excels all other tests as diagnostic and prognostic agents if the method that I have employed is carried out and one remains within the boundary line of maximum retention of blood urea.

It has not been my intention in this paper to lead one to believe that I have discarded the use of other tests for diagnosis and prognosis, because I have clearly demonstrated in the paper that there are certain conditions that befall the genito-urinary tract, under which the other tests must be employed in addition to blood urea, to determine the true status of conditions. From the foregoing information I have been able to draw the following conclusions:

CONCLUSIONS

1. In blood urea we have a valuable retention test to be used in the diagnosis and prognosis of urologic cases.
2. It may be employed in all urologic cases without any special limits.
3. Blood urea as a prognostic agent in urology is practically infallible, if employed by the method I have described.
4. It is a simple procedure and may be used to advantage when the excretory tests such as phenolsulphonephthalein, urine urea, etc., cannot give the desired information.
5. When relative kidney function is desired, it should be used in conjunction with the excretory tests.
6. In a case with a blood urea of more than 1 gm. per liter of blood, the prognosis should be considered grave, and less than 0.75 gm. as good.
7. An oncoming uremia may be diagnosed long before the clinical signs make their appearance, and before the excretory tests can give the information.
8. Its employment will materially decrease the percentage of mortality held against the urologist or general surgeon.

THE INFLUENZA EPIDEMIC IN CHICAGO

THE DISEASE AS A TYPE OF TOXEMIC SHOCK

ROBERT W. KEETON, M.S., M.D.
Instructor, Department of Pharmacology and Therapeutics, University of Illinois College of Medicine; House Physician, Cook County Hospital
AND
A. BEULAH CUSHMAN, M.D.
Instructor, Department of Ophthalmology, University of Illinois College of Medicine; Resident Physician, Cook County Hospital
CHICAGO

The following report is based on the cases of influenza admitted to Cook County Hospital, and on personal observations and experience in their treatment. We believe a careful statistical report of those cases is valuable for two reasons: First, it will serve to correct and amplify many opinions and conclusions which physicians dealing with a more limited set of cases have formed; second, it will aid in understanding some pre-epidemic obscure cases. For about eighteen months the term "atypical pneumonia" has been frequently used to designate cases which did not conform to textbook descriptions, but which have been increasing in numbers. Some of these cases made their appearance in the hospital over one year ago, and in the spring of 1918 constituted many of the so-called lobar pneumonias. They were admitted to the hospital and discharged under varying diagnoses, as bronchopneumonia, capillary bronchitis and epidemic mixed infections. We now know we have just passed through a period in which those more or less sporadic and obscure cases have grown into epidemic proportions.

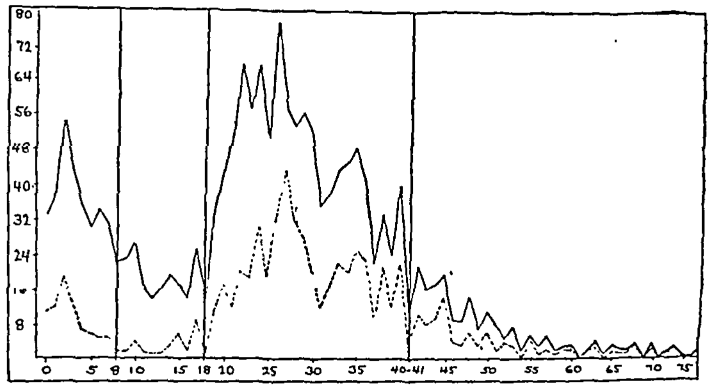

Chart 1.—Admissions and deaths with reference to age: solid line, admissions; broken line, deaths.

Two previous reports have appeared from the Cook County Hospital, one[1] dealing with the etiology and pathology primarily, and another[2] with one of the complicating factors (pregnancy). The present work is based on a study of 1,735 completed records in which the patients have been discharged, either through death or recovery. These were drawn from all ages and included males and females living under conditions reproduced in all large cities throughout the country. From an epidemiologic point of view, the statistics should furnish valuable supplemental data to those being reported from the Army camps.

[2] Woolston, W. J., and Conley, D. O.: Epidemic Pneumonia (Spanish Influenza) in Pregnancy, The Journal A. M. A., Dec. 7, 1918, p. 1898.

ADMISSIONS

Because of the epidemic nature of the disease and the rather limited hospital facilities, instructions were issued to the county and examining physicians to accept for the hospital only patients that were really ill. Under such a working rule the final hospital diagnosis showed the distribution of cases to be 38.2 per cent. of influenza with or without bronchitis, and 61.8 per cent. of bronchopneumonia.

Age as influencing the incidence is shown by Chart 1, and it will be noted that the density of admission falls into two groups, one terminating with the eighth year, and the other lying between the eighteenth and fortieth years.

According to sex, the percentage of males was 59.2, and of females, 40.8.

This is rather interesting from an epidemiologic point of view. The male population was much reduced by the Army drafts. The floating population that frequents the saloon and cheap lodging house and is subjected to untoward conditions of life had been largely eliminated by the "work or fight" ruling.

The females did not remain at home in greater proportions, because the prostration of the class of cases accepted was such that they would have been a burden on the family, rather than an aid. It is safe to conclude, therefore, that males were affected in larger numbers than females. This may mean that because of their more frequent contact with each other in crowded streets and cars, the opportunity for infection was greater in the male than in the female.

MORTALITY

The total mortality reported by Nuzum and his collaborators[1] was 31 per cent. This was figured on the basis of the receiving office records of admissions, and the deaths for the corresponding number of days. Our data, taken from completed records of discharged cases, shows the slightly higher figures of 39.3 per cent.

Age.—Reference to Chart 1 again shows a close similarity between the number of admissions and deaths. From a casual glance one might conclude that this was the only factor concerned. The density of admissions falls into four groups as shown by the vertical lines bounded by 8, 18 and 41 years. The death rate for each of these groups was: to 8 years, 26.6 per cent.; from 8 to 18 years, 18.5; from 18 to 41 years, 44.7, and above 41 years, 52.7 per cent.

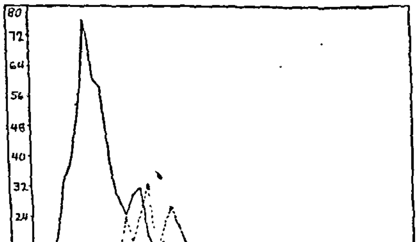

Chart 2.—Duration of bronchopneumonia from onset until discharge from the hospital by recovery, or until death: solid line, deaths from bronchopneumonia; broken line, recoveries.

In the light of the frequent comment that the children and old people stand the influenza much better than adults, it will be noted that old age is not a period of good, but of poor prognosis, while the lower mortality of youth is confined primarily to the years between 8 and 18.

Sex.—In the series studied, the deaths of males were 38.9 per cent., and of females, 40 per cent.

Attention has been called by Woolston and Conley[2] to the unfavorable effect of pregnancy on the prognosis. Since their data include approximately 100 pregnant women, it would seem that a female suffering from influenza uncomplicated by pregnancy has a chance of recovery equal to that of a male.

DURATION OF DISEASE

When a physician has exhausted all the means of physical diagnosis in attempting to judge the prognosis of a case, he finally consults the chart for the duration of the disease, before offering an opinion as to the ultimate outcome. With this idea in mind, the durations of sickness in both influenza and bronchopneumonia have been studied.

In bronchopneumonia, death (Chart 2) occurs as early as the third day. The maximum number is on the eighth day, from which point the decrease is rapid, until the sixteenth day. The level then gradually sinks to the twenty-eighth day.

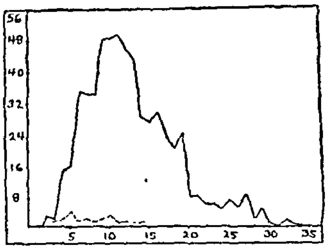

Chart 3.—Duration of influenza from onset until discharge from the hospital by recovery, or until death: solid line, influenza recoveries; broken line, deaths.

Recoveries began on the fourth day and lasted through thirty-three days, with the peak of the curve on the sixteenth day, and a maximum extending from the eleventh to the twenty-fourth day.

Deaths from influenza (Chart 3) were due frequently to an attack terminating a chronic process (as myocarditis, emphysema or cirrhosis of the liver) or developing in the course of pregnancy. Their number is too small to be significant.

Recoveries from influenza begin on the third day, the maximum period ending on the twentieth day, with the high point of the curve on the thirteenth day.

A period of further morbidity of from seven to fourteen days must be added before the patient was fit to resume his daily routine. It is safe to say that the economic loss in these severe cases amounted to from three to six weeks.

In a person ill with bronchopneumonia, the chances of recovery computed in terms of days of duration may be thus expressed: from four to eight days, 7 per cent.; eleven days, 19; fifteen days, 45; twenty days, 70 per cent.

DURATION IN THE HOSPITAL

The duration of the patient in the hospital before death is shown in Chart 4. The high percentage of deaths within from twenty-four to seventy-two hours after entrance indicates that their condition was already hopeless before entrance. Unquestionably the strain, discomfort and exposure associated with the transfer of many cases to the hospital not only reduced their chances of living, but hastened the impending end.

CLINICAL PICTURE

In examining the histories, we hoped first to establish those features of primary and secondary constancy, and finally those less frequent but still of great academic interest, in showing the protean manifestations of the disease.

The primarily constant features were asthenia amounting usually to prostration; headache; muscle pains chiefly located in the sacral region or the extremities, and cough or other evidences or respiratory irritation.

Those of secondary constancy were hemorrhages of some form: epistaxis, hemoptysis, which at times amounted to a pulmonary hemorrhage; bleeding from the gums; hematemesis; menorrhagia; metorrhagia, and hematuria; sore throat, not always a definite soreness, more frequently a dryness and irritation in the nose and throat, which presented on examination a dry, glairy, beefy red color; hoarseness; nasal discharge in infants; nausea and vomiting; cyanosis in adults, and pallor in children.

Less frequently there occurred pleuritic pain at the onset; abdominal pain; diarrhea; urinary retention; erythemas of various types, and deafness.

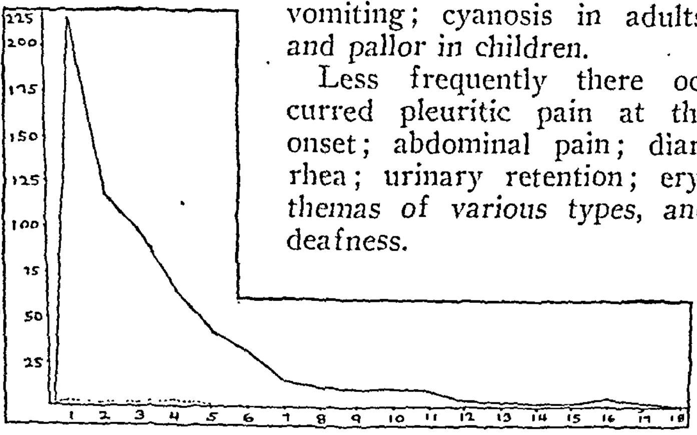

Chart 4.—Daily distribution of deaths with reference to the length of time in the hospital: solid line, bronchopneumonia; broken line, influenza.

The spleen was reported enlarged in only a very few cases. This may have been due to faulty observations, but we are inclined to think it a rather inconstant feature.

The onset was usually insidious, as outlined above. Less frequently it was so stormy that the patient could present with exact accuracy the details of its progress.

Blood Counts.—The exact relation of leukopenia to the disease is not clear in the textbooks. The physician busy with his daily practice has no data from which to formulate an expression of opinion. Our records showed 688 counts, of which an appreciable number were on the same patient on succeeding days. They were studied with reference to the duration of the disease, diagnosis of the cases, and the ultimate outcome as to life or death. The results are to be found in the accompanying table. The counts were tabulated for the day of sickness, and the percentages were computed from the number of counts on this day. The normal count was placed at from 7,000 to 9,000.

Influenza has a high (46.6) percentage of leukopenia in the early stages. With improvement, 24.3 per cent. of the counts were raised into a leukocytosis. During the whole period, more than half (62.2 per cent.) maintained a leukocytosis. The ranges of this leukocytosis lay between 9,000 and 15,000. Such an increase in the white count must be regarded as a favorable sign.

Bronchopneumonia.—In patients dying, the early counts (four days) showed a 50.1 per cent. leukopenia. If now the total counts in the normal and leukopenia column are contrasted in those recovering (53.7 per cent.) and those dying (65.4 per cent.), it will be seen that a balance of 11.7 per cent. exists in favor of the recoveries. Despite the occurrence of death, 22.3 per cent. of the counts were raised from a leukopenia or normal into a leukocytosis. The total average for the period showed no significant result. The lowest count was 900.

In patients recovering, the evident tendency to leukocytosis is shown throughout the course. This fact is more clearly seen when the succeeding counts are examined. The range of leukocytosis was found to be somewhat higher in this class of cases (from 15,000 to 20,000).

It may be concluded that even in the early stages of bronchopneumonia, a leukopenia points to a bad prognosis, and a maintenance of a low count cannot be looked on as other than a very serious symptom. In a few instances a drop was actually noted in the count on the day preceding death. This raises the question of the mechanism of the leukopenia. If it is a toxin that is stimulating negatively the hematopoietic organs, then the leukopenia in the milder cases may be taken to mean a persistence of unneutralized toxins. Crile[3] has called attention to a leukopenia as a diagnostic point in surgical shock. On such a basis, leukopenia developing terminally may be an expression of the more profound toxemic shock into which the patient is sinking.

Blood Pressure.—The blood pressures were taken in selected cases, one group presenting cyanosis with and without pulmonary edema, and another group with a high temperature presenting profound toxemia, but with no evidence of cardiovascular break.

Cyanosis is not an evidence of low blood pressure and does not bear any constant relation to it. Thus systolic pressures of 70, 85, 98 and 98 were recorded in patients who had no cyanosis. Even in the presence of pulmonary edema the pressure may be well maintained. Our records show pressures below 100 in sixteen cases, the majority of these being in the nineties; between 110 and 100 in eight cases, and above 110 in thirty-three cases. In fact, one is again impressed that a patient may maintain an apparently efficient blood pressure in the presence of a definite toxemic shock or at least on the verge of such condition, and that the blood pressure is of little value in determining the breaking point of the cardiovascular system.

BLOOD COUNTS

Duration	Leukocytosis	Normal	Leukopenia
Influenza, recoveries:			
Preceding maximum recoveries 5 days..	28.7	24.7	46.6
Maximum recovery period 6 to 18 days..	41.1	29.3	29.6
Total period	37.5	32.4	30.1
Bronchopneumonia, recoveries:			
Preceding maximum recoveries 6 days..	46.3	24.4	29.3
Maximum recoveries 7 to 18 days........	70.6	11.3	18.1
Total for 18 days................	62.2	16.1	21.6
Bronchopneumonia, deaths:			
Preceding maximum death period 4 days..	34.6	15.3	50.1
Maximum death period 5 to 18 days......	56.9	8.2	34.9
Total for 18 days................	41.3	13.5	45.2

COMPLICATIONS

We shall enumerate rather briefly some complications encountered, and speak in detail of one of the more unusual findings.

Bronchopneumonia.—This may be considered as either the subject under discussion or its most important complication. The fact that these pneumonic areas were at the onset usually centrally located explains the absence of pleuritic pain in the early stages of the disease. It was not until an extension of the consolidation involved the pleura that either pain or an effusion developed. The rather constant finding of fluid as reported by Nuzum and collaborators[1] in those patients dying early is simply an expression of the rapidity of the process. In our series, only twenty cases of pleuritic effusions were diagnosed and confirmed by paracentesis. Five of these patients later developed pus, and one a pyopneumothorax. In six other patients now convalescent, a diagnosis of thickened pleura has been verified by the fluoroscope and plates. It would seem, then, that the great majority run their courses without having the pneumonic process so situated as to involve the pleura.

---

[3] Crile, G. W.: Hemorrhage and Transfusion, New York, 1909, p. 75.

Otitis Media.—This, the next most frequent complication, occurred in eighty cases.

Mastoiditis.—Three cases developed, one of which was associated with facial nerve paralysis terminating fatally. Two patients recovered.

Parotitis.—There were six cases, suppuration developing in one.

Meningismus.—Nineteen cases presented all the signs of meningeal irritation. The spinal fluid was negative except for the increased pressure.

Meningitis.—There was one case in which gram-positive cocci were present in the fluid. The patient died.

Ulcerative Stomatitis.—There was one case with death.

Cervical Adenitis.—There were two cases.

Peritonsillar Abscess, Disease of the Antrum, and Osteomyelitis of the Femur.—Of each of these there was one case.

Surgical Emphysema.—There was one case involving the neck tissues of undetermined etiology.

Diseases of the Heart.—Myocarditis with decompensation and recovery occurred in only one case. The unfavorable effect of the disease on previously established heart lesions was to be expected. Of twenty such patients, only three who were suffering from a mild influenza recovered.

Superficial Infections.—Small abscesses involving scalp, nose, axilla and sacral regions were noted. A tendency to development of bedsores was evident. The tip of the ear sloughed off following a puncture for a blood count in one case.

Psychoses.—The exact data involving the number of postinfluenzal psychoses from our series of cases is not available. Dr. F. M. Fowler states that there were thirty-three admissions to female wards of the psychopathic division of the hospital; the onset was from three to five days after an apparently established convalescence from a bronchopneumonia; the mortality was 15 per cent., and the duration was from twelve to fifteen days.

Acute Laryngeal Obstruction.—Of this there were six cases, in patients aged, respectively, 1 year, and 1½, 2, 4, 6 and 50 years. The condition developed in four cases at the height of the disease, in one case in convalescence, and in one case ten days after discharge. The symptoms were those of a typical obstruction: cyanosis, laryngeal stridor, retraction of the episternal notch and xiphoid process; and nonproductive and irritative cough, immediately relieved by intubation. Cultures from the throats, and intubation tubes were negative for diphtheria. Antitoxin was given in two of the first cases. Tracheotomy had to be performed eventually in all of the cases. From the tubes, large amounts of pus and serosanguineous mucus was obtained. Pathologic examination revealed an intense tracheobronchitis extending upward, involving the larynx with consequent edema. Death resulted in from eight to seventy-two hours in five of the cases. One patient survived and is still in the hospital.

DIAGNOSTIC DIFFICULTIES

Since the influenza cases were entered and handled through the contagious branch of the hospital, the problem of an accurate diagnosis carried with it a greater element of urgency than in most medical cases.

At the onset, typhoid was diagnosed in three cases that later proved to be influenza. Another case was seen by several of the attending men, who were divided in their opinions between miliary tuberculosis and influenza. Roentgenograms favored influenza. The outcome with recovery and the development of a complicating antrum established the diagnosis.

In fifteen cases these questions arose: Is it a pulmonary tuberculosis, on which an influenzal infection has been grafted? Is it a pneumonic phthisis? Is it a rapidly advancing tuberculosis without appreciable consolidations? In one of these fifteen cases the patient, a lad of 17 years, entered the hospital with a syndrome that made a diagnosis impossible. Roentgenograms of the chest furnished no conclusive evidence. Two blood cultures were positive for a staphylococcus. Improvement followed for a while; then a reappearance of the symptoms occurred. At this time the chest plates showed an unmistakable miliary tuberculosis. Meningitis terminated the course. Evidently an influenza had lighted up a healed or latent tuberculosis.

Lobar pneumonia was still being handled in the medical wards of the general hospital. Under what conditions were cases to be continued in medical wards as lobar pneumonia? With consolidation evident and a leukocytosis present, all cases presenting a history of sudden onset with chill and pleuritic pain were retained in medical wards as lobar pneumonia. The nasal discharge in the children resembled nasal diphtheria, while the erythemas were quite suggestive of scarlet fever.

Theoretically, pertussis in children and smallpox in adults before the appearance of skin eruptions might be mistaken for influenza.

TREATMENT

Before one can satisfy oneself that therapy is directed along rational lines, one must appreciate the mechanism of the perversion of the physiologic processes. Every one appreciated that in those dying, failure to continue life must be attributed to the exhaustion of the cardiovascular system. The cyanosis, the pulmonary edema, the weak second pulmonic sound, the enlarged, tender liver, increasing dyspnea, and the low blood pressure in certain cases were all evidence that the toxins were destroying the one vital function, the circulation.

During the past four years under the guidance of the Medical Research Committee of this country and Great Britain, the phenomena of shock have been clarified. The views as to its nature and the literature are completely given in two readily available articles by the

British Medical Research Committee[4] and by Cannon.[5] Briefly, shock may be precipitated by three classes of agents: surgery, trauma and toxins; but minor variations may exist in the picture, depending on the etiologic agent. Cannon speaks of shock as an "exemia." The blood pressure is a resultant of heart action, vasomotor control and blood volume. That the first two factors are not at fault has been abundantly demonstrated. The evidence for this view is stated by Mann.[6] That the blood volume factor is the important thing in surgical and traumatic shock has been shown by Cannon, and more recently by Mann.[7] Guthrie,[8] in studying one form of surgical shock, induced by excessive stimulation of nerves, was unable to confirm the results of other investigations that the quantity of blood fluid is reduced in the capillaries. On the contrary, he found some evidence of entrance of liquid into the blood. The rather difficult task experienced by other workers in inducing shock by this procedure raises the question of its identity as compared to that induced by other methods. Some difference of opinion exists as to whether this loss of blood from the available circulation is due to its accumulation in the veins or whether it has been lost by outflow into the tissues and lymph spaces through the capillary walls. The latter is the more probable view.

Dale and Laidlow[4] produced shock by the use of histamin, which is the amin of histidin, one of the building stones of the protein molecule. The conversion of amino-acids into amins is distinctly a type of bacterial activity, and can be reproduced in vitro. We may regard, therefore, that the toxins at work are akin in their activities to histamin. It was shown that at the low point of the blood pressure practically 50 per cent. of the blood plasma had been lost in the capillary region. The secondary results of this are slowing of the blood stream through the increased viscosity, and poor oxygenation of the tissues. Poor oxygenation of the tissues terminates in a condition of acidosis, through the accumulation of intermediate split products. The acidosis affects unfavorably the permeability of the capillary walls. The situation, then, is transudation of the plasma under the influence of the bacterial toxins, slowing of the blood, greater tax on the heart and vascular system, poor oxygenation, acidosis, more transudation, and so on ad infinitum.

Granted a severe infection, the problems of treatment are the prevention as far as possible of the shock state, and the treatment of the established state.

The one element in prevention that lends itself to ready therapeutic application is a dilution of the toxins. Those patients who were evidently prostrated, but were not in a shock state, and in whom sufficient nursing care was available, showed improvement, when fluids, in maximal quantities, were given. These were given by mouth, discontinuous rectal administration by the drip method, and hypodermoclysis. The rationale of the use of the alkalis had not appealed to us; so while we used them in this stage, we believe that the concentrations used were too small to show results. When shock developed, treatment was of little or no avail, but we wish to record certain measures which we feel may be of distinct harm.

Venesection.—In the cyanotic cases, some of the attending men believed that a venesection should be performed, followed by hypodermoclysis. This was advocated with the idea that a certain amount of toxin would be mechanically removed, and that probably relief might be furnished to the heart; so the parting word of advice given by them was to go carefully on the amount of fluids returned to the body. Theoretically the method should be valuable in removing some of the toxins; but instead of relieving the heart, it was only adding to its burden. For the heart was failing not because of excessive peripheral resistance but because there was not enough blood on which it might contract and maintain its coronary circulation. Venesection was performed in fourteen cases. Thirteen of the patients died, and the fourteenth is now suffering from a rather serious psychosis. One died during the operation, and in at least three others the condition was so changed that death occurred in an hour's time. This is exactly in line with the experience reported by those dealing with surgical shock, that even a small hemorrhage reduces the patient's chances of recovery.

Administration of fluids in this stage is difficult. By intravenous injection and hypodermoclysis the fluid may be introduced into the circulation, but it leaks out immediately through the capillaries. Rectal absorption fails in many cases. The water is expelled or distends the patient, adding to his difficulties.

Glucose Administration.—A series of cases has been reported by Litchfield[10] in which the patients were treated by intravenous injections of hypertonic glucose solution. In this work an occasional reaction was reported in which high temperatures with chill occurred. We gave a 10 per cent. glucose solution in two cases, and in each the temperature rose from a level which was only moderate to 107, and death followed in five hours. We were rather discouraged, for frankly at the time that the solution was given to one patient we felt that she had a chance of recovery by the more conservative methods of treatment. That such injections, even when practiced in a number of cases sufficiently large to rule out these so-called accidents, may be harmful is indicated by the findings of Mann[7] in a recent piece of work. He produced shock by tying off the venous return from the leg of an animal and allowing the arterial supply to remain intact. The animals went into shock after varying periods. If, now the ligatures were removed, the shock deepened instead of improving, his interpretation was that in the period of ischemia there had been formed certain products which, when thrown back into the circulation, were contributory factors in maintaining the shock. It is just possible that the glucose may wash into the efficient circulation a sufficient dose of toxic matabolites to act very injuriously.

Digitalis and atropin seemed to be the most efficient of the drugs used. The indications for digitalis would seem to lie in its action on the heart and in its power of transferring the blood from the venous to the arterial side.

Atropin relieved many patients of their cyanosis, and, we believed, increased the chances of recovery in those patients in whom it was used. The beneficial effect of atropin in large doses as shown in the epidemic at Great Lakes Naval Training Station has been reported by Ridge.[11] The only suggestion we have for its apparent value over pituitary solution lies in the well known experiment of Auer[12] in which he showed that atropin prevents death in guinea-pigs subjected to an anaphylactic shock by preventing the stenosis of the bronchioles. The cyanosis may be due to moderate narrowing of the bronchioles already filled with mucous secretion. That it is of value in beginning pulmonary edema is a matter of clinical experience. If it has an action on the permeability of the capillaries of the lungs, stopping the outward flow of fluid from the blood, it is no great stretch of analogy to transfer the same line of reasoning to all of the tissue capillaries of the body. Hence, it may be regarded as a drug that is acting at the site in which the perversion of the physiologic processes is occurring. In grosser terminology, it might be said to have more or less "specific" action in this class of cases.

CONCLUSIONS

1. The blood count early in influenza may show a leukopenia or normal count in over 50 per cent. of the cases, but with recovery this is changed to a leukosytosis of from 9,000 to 15,000.

2. The blood count in bronchopneumonia, in those recovering, shows early a very transient period of leukopenia; in those dying, a much higher percentage of leukopenias is found and a greater tendency to its persistence. A normal count or a leukocytosis may be changed to a terminal leukopenia in fatal cases. The range of leukocytosis lies between 15,000 and 20,000.

3. The blood pressure is no index of the state of the cardiovascular mechanism. Cyanosis bears no constant relation to blood pressure.

4. In the acute cases the patients are really suffering from a toxemic shock.

Health in City and Country.—Commenting on and attempting to give reasons for the somewhat better showing of city men over country men in the recent military draft examinations, Dr. L. D. Bristol, state health commissioner of Maine, in an address before the Massachusetts School for Health Officers (May, 1918) thus summarizes the essentials of public health administration in rural districts: (1) a thorough study of rural sociology in general; (2) a special study of rural sociology based on the economic interests of the state in question; (3) public health education in rural districts leading to a definite demand for, and financial support of, an adequate local health organization; such education should be carried on by (*a*) the state department of health; (*b*) the rural schools; (*c*) the agricultural colleges. The latter should give required courses in hygiene and public health under the direction of thoroughly competent sanitarians, and should educate the rural population through extension courses in order to develop rural public health leadership. (4) As soon as possible, the establishment of health unions made up of two or more towns, for the employment of union health officers and nurses, who, in some manner, should be responsible to the state health organization. Towns or cities over a certain population which desire to employ their own full-time health officer should be exempt from the union plan. (5) The extension of all laboratory facilities for the state department of health so that through branch laboratories the rural districts might have close at hand all of the advantages of modern diagnostic and prophylactic methods. (6) Extension of federal and state financial aid until such time as the local rural community can assume the entire financial responsibility.—*Bulletin of the State Department of Health of Maine.*

POSTCILIARY SCLERAL TREPHINING FOR ACUTE GLAUCOMA *

A. E. EWING, M.D.
ST. LOUIS

As the several procedures in the case reported below have resulted in a blind eye, the material is offered only as a study in the intricate problem of glaucoma.

REPORT OF CASE

A healthy unmarried woman, aged 57, during the course of a stye two weeks before I saw her, noticed that her right pupil was large and that the vision was not so good as formerly. Since then she had been using physostigmin (eserin), prescribed by a physician, without relief.

July 18, 1917, in the left eye the tension as determined by the Schiötz tonometer was 20, and the vision $^{20}/_{20}$ with correction 1.75 spheric. There was a large, old retinochoroidal atrophic spot in the lower nasal portion of the fundus. The field was normal. In the right eye the tension with the Schiötz tonometer was 57, and the vision $^{8}/_{150}$. The cornea was steamy over the central portion. The pupil was 6 mm. in diameter. There was a shallow anterior chamber. Only a dim view could be obtained of the disk and vessels. There was a small, old retinochoroidal atrophic spot in the lower nasal portion of the fundus, and a larger one in the temporal portion of the fundus. The field was practically confined to the temporal half, and in this half was greatly restricted.

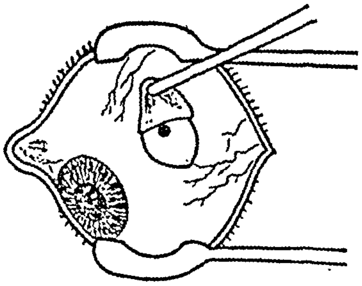

Fig. 1.—Postciliary scleral trephining for acute glaucoma: Location of the wound in the neutral region, midway between the superior and the external rectus muscles.

With the aid of physostigmin and pilocarpin the cornea and media cleared to the extent that arterial pulsation on the disk was readily observed and there was marked cupping of the disk, which seemed to be physiologic. Also the vision rose to $^{20}/_{60}$, but the pupil remained wide, 6 mm. in diameter, under repeated instillations of physostigmin. The nasal examination by Dr. Sluder showed a general chronic atrophic rhinitis of low grade. The blood pressure was 140, systolic.

July 25, as there was no evidence of permanent improvement, a postciliary scleral trephining was performed in the upper temporal portion of the globe 7 mm. from the corneal margin, the operation being one that has already been described,[1] a diagram of which is here reproduced (Fig. 1). In this procedure the eye is first anesthetized with holocain, 1 per cent., and cocain, 5 per cent., and a minim of 1 per cent. cocain solution is then injected hypodermically at the site of the intended opening in the sclera. After from three to five minutes an 8 to 10 mm. conjunctival flap is raised from below and the wound is located at the center of the base of this flap, which is placed preferably in the neutral region, either between the external rectus and the superior rectus, or between the external rectus and the inferior rectus muscles. The flap may be dissected from the sclera over its whole area, or the conjunctiva may be dissected to Tenon's fascia only as far as to the base of the flap, and here with scissors it may be cut through the fascia to the sclera at the site of the wound to be trephined. It has seemed that better drainage was obtained by the last method.

In this particular case the entire flap was dissected through to the sclera, and with a 2 mm. trephine the sclera was then trephined through the choroid, 7 mm. from the corneal margin. This membrane bulged into the wound but did not rupture. The conjunctival flap was then replaced by means of a suture at the apex, and the eye was cleansed with physiologic sodium chlorid solution and bandaged. Following the operation there was no appreciable reduction in the tension, as determined by palpation with the fingers. The operation was practically painless, and there was no subsequent pain. At the time of the first dressing, forty-eight hours later, the globe was very quiet, the cornea clearer than at the time of the operation, the pupil round and central and 7.5 mm. wide, there was a good reflex from all portions of the fundus; there were no details. Vision was reduced to *fingers at 1 foot*, eccentric to the right. There was no appreciable change in the tension of the globe, but the patient remarked that the eye was "more comfortable than it had been in three weeks," because it had felt as if the globe was "too large for the socket." This discomfort had ceased. Under the constant use of physostigmin, 0.5 per cent., the vision returned to 20/60, eccentric to the right, during the succeeding four weeks, and the field was somewhat reduced in size. There was marked protrusion of the conjunctiva over the trephined area, and the opening in the sclera was readily seen through the conjunctiva and shown to be clear by transmitted light.

* Read before the Section on Ophthalmology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

[1] Ewing, A. E.: Am. Jour. Ophth., July, 1917.

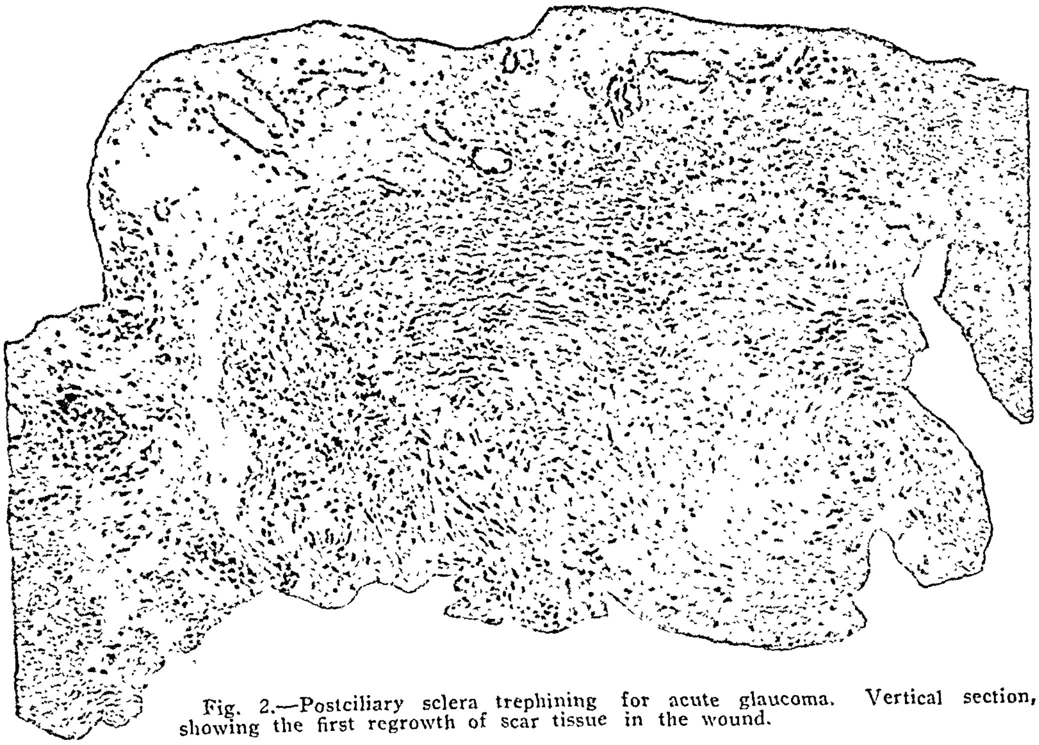

Fig. 2.—Postciliary sclera trephining for acute glaucoma. Vertical section, showing the first regrowth of scar tissue in the wound.

September 19, the tension was 60 mm. of mercury by the Schiötz tonometer. September 24 it was 55; there was no discomfort; the media were clear; there was marked arterial pulsation on the disk. Vision was 20/120, eccentric to the right.

September 25, I raised a conjunctival flap over the trephined area and discovered that the apparent protrusion of the conjunctiva, which I supposed was a delicate cystic scar, actually consisted of dense tissue formed from the sclera, a vertical section of which is shown in Figure 2. It was removed by means of a Graefe knife on the flat in the plane of the sclera. It did not seem to be connected with the choroid, which was later slit open by the knife on the flat, also in a plane with the sclera, and this incision in the choroid was followed by three large drops of vitreous, which were removed in succession with the spatula until it ceased of itself to flow. This left the globe very soft.

September 26, the globe was soft; the media were clear; there was no arterial pulsation on the disk; there was a small, diffuse, nearly central retinal hemorrhage. Vision was fingers at 4 feet. The pupil was 6 mm. in diameter, not affected by physostigmin. During the following few days other small peripheral hemorrhages appeared in the retina and several minute adhesions of the pupillary margin to the lens became evident, yet there was no other indication of iritis and no cyclitis.

October 3, vision was 20/240, eccentric. Tension by the Schiötz tonometer was 9. The media were clear. There was no arterial pulsation on the disk. The globe was quiet. There was no tenderness on pressure.

Now follows the extremely interesting part of this experience, and it demonstrates that acute glaucoma is not cured by direct loss of vitreous. Also it demonstrates that glaucoma is dependent on the drainage of the aqueous, and that this drainage may be by way of the vitreous, provided it could be sufficiently maintained by this route.

October 5, the vision of the right eye was motion of the hand at 6 inches. Tension by the Schiötz tonometer was 51. The fundus details were very indistinct. Following the employment of physostigmin salicylate, 1:240, twice during the next three hours, vision became 20/150, and the media became sufficiently clear to detect marked arterial pulsation. This pulsation ceased after massage of the globe over the wound, the eyelids being closed, but without further improvement in the vision.

October 7, vision was 5/150. The globe was hard, and there was marked conjunctival protrusion at the site of the wound. Incision through this was followed by a free flow of aqueous, no vitreous, and reduction of tension to below normal.

October 9, vision was 10/38. There was no arterial pulsation on the disk, and there were *no new hemorrhages*.

October 10, the patient reported an uncomfortable night. The eye was painful, the globe hard, the disk blurred; there was a mere outline of the vessels. Vision was 3/66. The conjunctiva was distended at the site of the wound. I incised the distended bleb with a sickle needle. One hour later, vision was 10/48, the media were clear; there was a clear view of the disk and vessels. There was no arterial pulsation, the globe was soft, and there were no fresh hemorrhages.

October 11 and 12, vision was 10/38, the media were clear, and there was no arterial pulsation.

October 13, the patient felt severe pain for several hours. Tension was high. The disk was blurred. Vision was 5/75. The conjunctiva at the site of the wound was distended. Following incision there was free discharge of aqueous, no vitreous, and immediate relief from pain. Half an hour later, the media were clear. There were no new hemorrhages. Vision was 10/38.

October 15 the condition was similar. Incision was made with similar results.

October 17, vision was 1/192. Tension was high. The disk was indistinct. There was subconjunctival evacuation of aqueous from the site of the wound. Ten minutes later the tension was below normal. The media were clear. Vision was 10/48.

October 18 there was similar refilling of the globe. Incision was made with similar results.

October 22 and 23 there were repetitions of this.

October 29, vision was 10/192. I repeated the scleral trephining after partially elevating a thin conjunctival flap. The globe was quiet except in the region of the wound, where there was moderate conjunctival infiltration. On this account the dissection of the flap was difficult, as the conjunctiva was very friable. Following the removal of the trephined "button," there was a free flow of aqueous, no vitreous; suture was omitted. A reproduction of a vertical section through this trephined "button" is shown in Figure 3, and again demonstrates a firm fibrous scar.

November 1, vision was 10/38. Tension was normal. The media were clear. There was no arterial pulsation on the disk. There were no new hemorrhages.

November 7 the field was telescopic. Vision was 10/120. There was marked arterial pulsation. The media were clear. The conjunctiva over the wound was distended. Immediately following incision, the vision was 10/60.

After this, as the media remained clear, although the arterial pulsation on the disk returned, pilocarpin and physostigmin and massage were relied on for controlling the pulsation, which usually ceased temporarily with their employment.

Jan. 9, 1918, vision was reduced to hand movements at 1 foot. There was nothing to account for this change except the continued increased tension. The media were clear, there was arterial pulsation on the disk, and the globe was entirely quiet.

January 12, postciliary scleral trephining was performed with a 2.5 mm. trephine in the upper nasal portion of the globe. The scleral "button" split from the deeper portion of the sclera just as the choroid was approached. The remaining sclera was teased through to the choroid without rupture of the choroid over a space 1.5 mm. in diameter. The conjunctival flap was replaced by suture. There was no apparent relief to the tension. No pain followed the operation.

January 16, vision was 0. The media were clear, the globe quiet, there was moderate arterial pulsation, tension was as before operation, there was no choroidal reaction, and the eye was entirely comfortable.

February 23, although the globe was entirely quiet and comfortable, an incision was made in the wound first trephined to demonstrate whether any vision might return after so long an interval of blindness. The media were clear. There was moderate arterial pulsation on the disk. Tension by the Schiötz tonometer was 54. This incision was made first through the conjunctiva and then through a firm tissue protruding from the scleral wound. There was a free flow of aqueous, but no vitreous. Arterial pulsation on the disk ceased immediately. For the first time in this series of tappings of the globe there was a slight flow of dark pigmented fluid from the wound into the lower portion of the vitreous. This seemed to be a serous fluid stained with hematin or with pigment from the choroid or retina. It ceased immediately. Four hours later the arterial pulsation had become reestablished. There was no return of vision.

March 2, the globe was entirely quiet and comfortable, the pupil 6 mm. in diameter, the media clear, arterial pulsation on the disk, a small hemorrhage of the retina below the disk, a little floating exudate in the vitreous, and moderate conjunctival distention at the site of each trephined wound.

March 8, the fundus was quiet, the media clear, the globe entirely quiet and comfortable, the pupil 6 mm. wide, slight consensual response of pupil to light. Tension by the Schiötz tonometer 70, which was 13 mm. higher than before the several operations, moderate arterial pulsation on the disk, no change in the cupping of the disk, and the globe entirely quiet and comfortable. No medicines had been used during the last two weeks.

COMMENT

The case has ended unfavorably, and is unfavorable to this mode of treatment for acute glaucoma, if the condemnation of such treatment in the future is to be based on the result from one case. In my own hands cases just as favorable for operation, and even more favorable, have ended in the same way by methods considered generally as the best for glaucoma operations, namely, the iridectomy of von Graefe and sclerocorneal trephining. The experience here indicates that safety in glaucoma depends on the drainage. If drainage can be obtained by this method, it is safest of them all, because there is no danger to the lens.

The several procedures in the case demonstrate that:

1. The removal of vitreous in such quantity that the tension of the eye is far below normal is no more a cure for glaucoma than is the removal of the lens.
2. Drainage may be established by way of the vitreous chamber.
3. A trephined wound in the sclera is closed by newly formed fibrous tissue, in the same manner as a trephined wound at the sclerocorneal margin.
4. A trephined wound of the sclera in glaucoma is not a more dangerous wound than a wound in the sclerocorneal margin.
5. The clouding of the cornea and the vitreous, and the arterial glaucomatous pulsation on the disk, may be instantly relieved by drainage from the vitreous, with immediate restoration of vision.
6. The "full feeling" and the pain of acute glaucoma are relieved by sclerocorneal trephining, even though the choroid is not disturbed and there is no apparent lowering of the tension.
7. The lens is not affected by the operation.
8. Miotics are of as great value following the operation as before the operation.

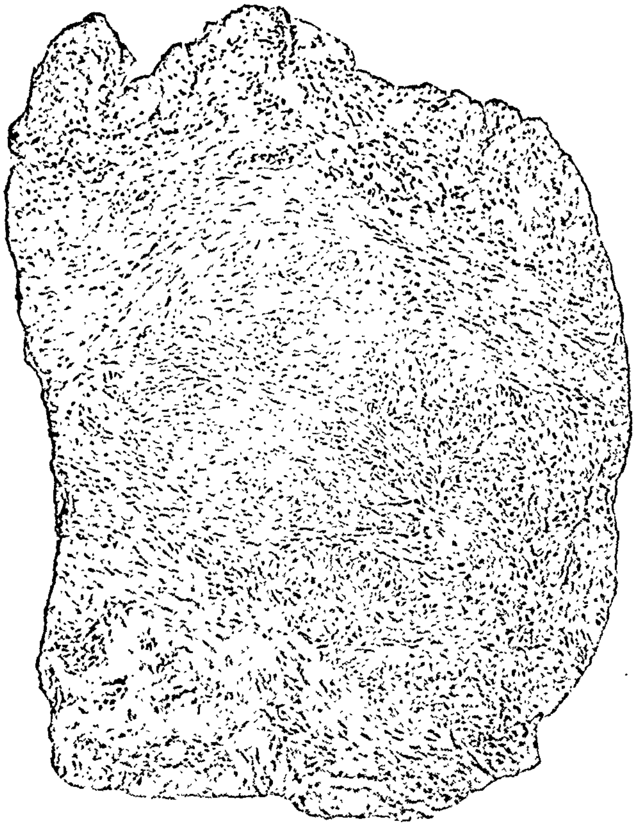

Fig. 3.—Postciliary scleral trephining for acute glaucoma. Vertical section, showing the second regrowth of scar tissue in the wound.

9. A painful glaucomatous eye will become comfortable after postciliary scleral trephining without visible operative defect, and without material lowering of tension.

Query: What are the compensatory avenues in the circulation in an eye in which there was pain and marked blurring of the media with the tension at 57, to cause it to become entirely quiet and comfortable, media clear and no appreciable change in the cupping of the disk, with the tension at 70?

ABSTRACT OF DISCUSSION

Dr. William F. Hardy, St. Louis: Dr. Ewing stated that a wound in the sclera is not more dangerous than one at the corneoscleral margin. In my opinion it is less dangerous. Last summer I performed a number of operations through the sclera by various methods, to note the length of time such wounds stay open, and the manner in which they heal. It was found impossible to delay or prevent the scleral wounds from healing; they healed very promptly no matter what method of operating was chosen. They remained patulous for possibly a week, after which they gradually filled in with dense fibrous tissue, and at the end of the month were completely healed. Dr. Ewing, therefore, has added evidence to the fact that posterior drainage operations are of temporary effect only, but are poor reeds to lean on for permanent effects in glaucoma.

Dr. Arthur E. Ewing, St. Louis: Since beginning this work about a year ago I have performed half a dozen of these operations in cases of chronic glaucoma, one a case with a tendency to iritis, and one a case of acute retinal separation. In each of the cases there is a protrusion at the site of the wound, a very large protrusion in a case in which a 3 mm. trephine was employed, too large to be sclera or newly formed scar tissue. In contradistinction to this, in the case with retinal separation, there was no protrusion at the site of the wound, the globe being subnormal in tension. The same condition obtained in the case of chronic glaucoma with a tendency to iritis, the tension of which was 40, but became subnormal after the operation and remained subnormal. This fact, that there is no distention without intraocular pressure, indicates that there must be some form of drainage.

TREATMENT OF NEURALGIA OF THE FIFTH NERVE BY INJECTION OF THE GASSERIAN GANGLION *

H. H. MARTIN, M.D.
SAVANNAH, GA.

The injection of the ganglion of Gasser through the foramen ovale for the relief of trigeminal neuralgia has passed beyond the experimental stage and will eventually supersede surgical extirpation of the ganglion, division of the sensory root, peripheral and nerve trunk injection, and other more or less unsatisfactory procedures. The operation is, of course, a very delicate one and requires, in addition to thorough knowledge of the topography of the parts, some surgical skill and dexterity; the needle will necessarily pass very near to important blood vessels, principally the internal maxillary artery, which lies in close proximity to the inferior maxillary nerve in the sphenomaxillary fossa and sends a small meningeal branch through the foramen ovale.

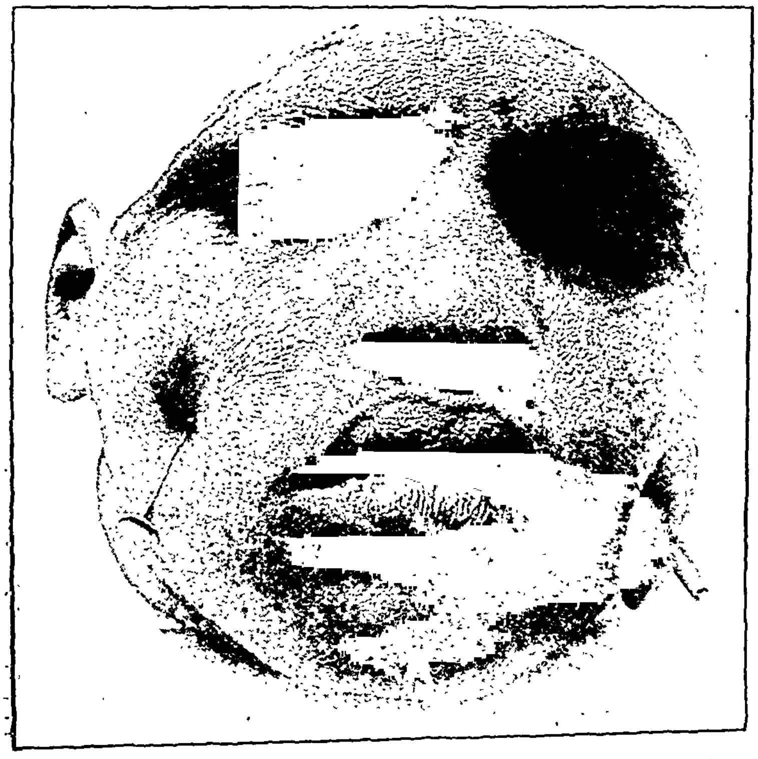

Fig. 1.—Left side shows needle in correct insertion. Right shows stylet displaced outward by postmortem contraction of skin.

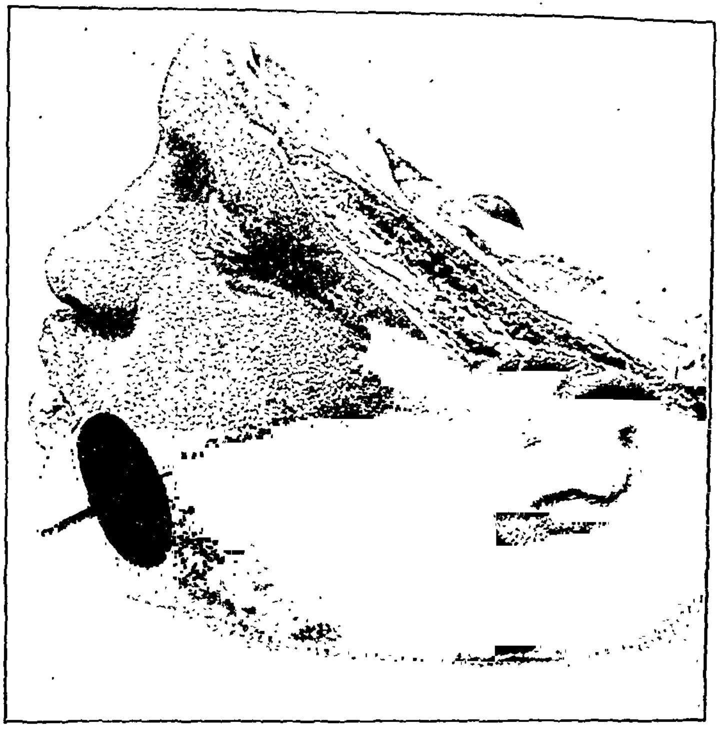

Fig. 2.—Same as Figure 1 in profile.

If improperly directed, the needle may enter the foramen spinosum, the jugular foramen, or an anomalous foramen transmitting an emissary vein known as the foramen Civinini, occasionally found just below the foramen ovale. If the needle is passed too far through the foramen ovale, possible injury might occur to the cavernous sinus or even the internal carotid, both of which are in intimate relation with the ganglion. But all such accidents can be safely guarded against; and the procedure, though a formidable one, is not so formidable as the surgical extirpation of the ganglion, while the desirable results are equally good and the undesirable results, such as paralysis of other cranial nerves, weakness of the muscles of mastication, and neuroparalytic keratitis, are never so bad.

The history of this operation, like many others, is one of evolution, and dates back to 1903, when Schlosser, an ophthalmologist of Munich, discovered by chance that subcutaneous injections of alcohol in or about an offending nerve afforded prompt relief from pain.

This idea has been taken up and elaborated on by many investigators in France, England, Germany and America, including ophthalmologists, rhinologists, neurologists, general surgeons and others, until there has been evolved a very simple method of injecting the ganglion of Gasser through the foramen ovale, which can be acquired by any one who will give sufficient time to experiments on the cadaver.

The indications for injection of the gasserian ganglion are the same as those for gasserectomy, namely, severe trifacial neuralgia, for which the cause cannot be discovered, or if discovered, cannot be removed. There are no serious contraindications; heart disease, high blood pressure, kidney lesion, etc., while increasing the seriousness of the situation, are not contra-

---

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

indications. Some measure for relief is necessary, and the injection is less dangerous than gasserectomy.

The finer distinctions between so-called essential neuralgia, postherpetic neuralgia, etc., have no place in this paper, which is limited to treatment; but I desire to say in passing that I do not believe that any of the procedures enumerated in the first paragraph of this paper will be of any benefit in a painful "tic" having its origin proximal to the ganglion of Gasser; on the contrary, those directed to the nerve trunks often aggravate the condition. The surgical or chemical destruction of the ganglion cells, however, will often give temporary relief from pain.

Therefore, given a case of painful "tic," the question arises as to what is to be done. Internal medication, massage, radiotherapy and electrotherapy have all been tried in the balance and found wanting. We have remaining the destruction of the central ganglion or of the nerve branches either surgically or with chemical solutions. It is my opinion that surgical methods should be abandoned in favor of those based on the direct application of chemicals calculated to destroy either the ganglion cells or the conducting fibers, and of these, the former is to be preferred, because the ganglion cells are the more vulnerable, as shown by the immediate positiveness and longer endurance of the results. Of the chemical agents that have been employed for this purpose I may mention osmic acid, chromates, formaldehyd solution in glycerin, phenol (carbolic acid) or menthol, chloroform, ether, antipyrin, salicylates and quinin salts, all of which have been abandoned in favor of alcohol in various strengths (from 70 to 95 per cent.). Also there are various chemicals which will give a temporary analgesia and anesthesia as well without destruction of nerve tissue, the chief of these being, of course, the cocain group.

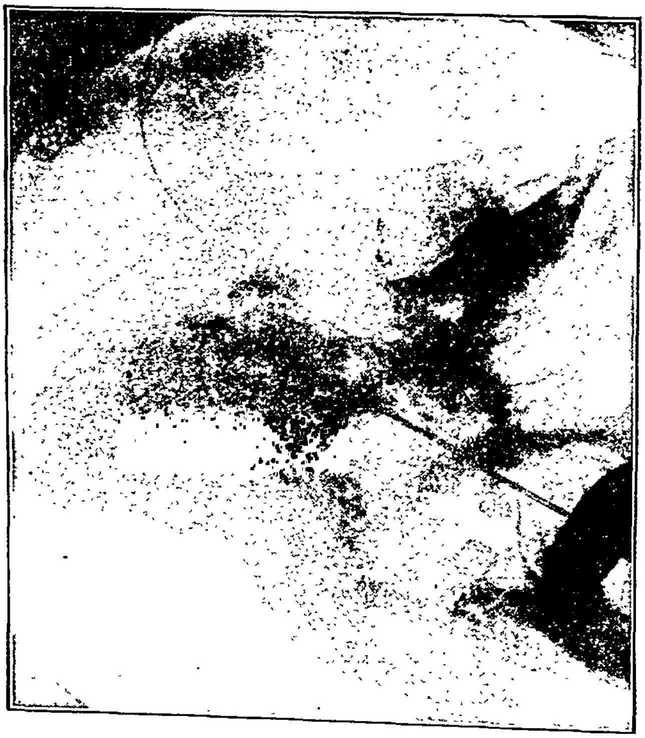

Fig. 3.—Right side shows needle in correct insertion with point in the ganglion. On the left side a wire has been passed through the needle and through left cerebrum with the idea of entering the lateral ventricle by this route to ascertain what structures might be injured.

The trigeminal divides at the gasserian ganglion into three principal trunks, the ophthalmic, the superior maxillary and the inferior maxillary. The ophthalmic divides into three terminal branches, the superior maxillary into six, and the inferior maxillary into seven; all sensory excepting the latter, which is mixed, carrying motor fibers to the muscles of mastication.

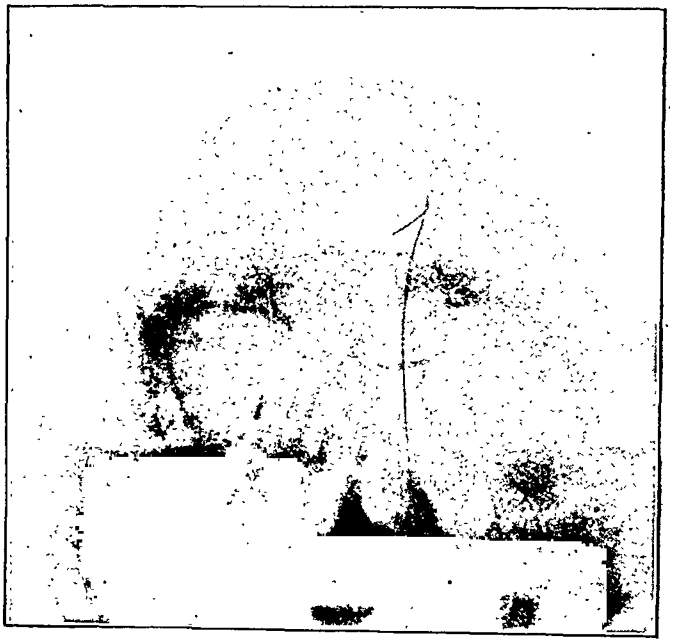

Fig. 4.—Same as Figure 3, front view. Note wire passing through posterior horn of left lateral ventricle and out at the vertex. So far as could be determined on the cadaver, no important structures would be endangered through entering the ventricle by this route. Right side shows point of needle resting in the ganglion.

In a recent paper, Sicard contends that alcohol nerve blocking treatment is adapted only to what he describes as essential neuralgia, differentiating thus: If the pain keeps up continuously, or if there is concomitant anesthesia of skin or mucosa, it is not essential neuralgia; or when the neuralgia comes on abruptly in all the three branches at once, or when other cranial nerves are involved and there are trismus, hemiatrophy of the tongue, etc. These forms of neuralgia are secondary, and injection of alcohol not only does no good but may even aggravate them. Hence it is necessary to have the patient examined by specialists in the nose, ear, eye and teeth, before assuming that a trigeminal neuralgia is of the essential type. Migraine must also be excluded, as also the neuralgia after herpes zoster. He warns us also against the neurasthenics.

I quite agree with this conclusion so far as it applies to injections into nerve trunks or branches; but injections into the central ganglion of the trigeminal system, or, better still, injection into the sensory root, has in my opinion a larger application than nerve blocking per se, and is a justifiable procedure in all cases of painful "tic" not otherwise relievable. I have never known of its doing serious harm when properly performed. There is always a very marked temporary relief, and it can be repeated ad libitum.

The technic of the injection is simple in the extreme, but ability to locate and enter the oval foramen can be acquired only by extensive and patient trials on the cadaver; but in every sense of the word it is eminently satisfactory both as to the accuracy with which it can be accomplished and as to the results.

If pain is limited to the area supplied by the third branch only, the injection can to a certain extent be limited to this branch; but if the first or second branches are involved, the needle should be inserted into and through the corpus of the ganglion until the point has penetrated the sensory root. This can be accomplished with a reasonable degree of accuracy. It is my practice to attempt this in every case. The only serious consequence involved is a neuroparalytic keratitis which in my experience occurs in about 30 per cent. of all successful injections, but rarely involves the deeper layers of the cornea, and in most instances recovers in due time without injury to the eye.

Wilfred Harris of London, who is one of the pioneers of direct injection of the ganglion through the oval foramen, says:

> When first I practiced injection of the foramen ovale on the dead body, I found, practically invariably, that when the needle point was placed within the nerve at the lips of the foramen, without pushing the needle through the foramen, injection of solution of methylene blue infiltrated the whole gasserian ganglion, the stain even surrounding the walls of the cavernous sinus, and even spreading down the anterior surface of the pons. Clinically I have thus injected the ganglion in scores of cases, anesthesia first appearing over the third division; and as more alcohol is injected, a few drops at a time, the anesthesia spreads over the second and first divisions until, after using from 1 to 1.5 c.c., the whole territory of the fifth nerve has become anesthetic. The patient indicates this spread of the alcohol by slight burning pain being felt around the eye and top of the head, and on testing with a pin there will be found total anesthesia to pin-prick and to pressure over the whole front of the head on one side, including the eyeball. If the alcohol has been slowly injected a few drops at a time, the anesthesia being tested after each injection, this total anesthesia will begin to fade away after a lapse of five or ten minutes from the first and second divisions, and an hour or so later, or the next day, there will be found slight analgesia on the forehead and cheek only, while total anesthesia persists over the third division.

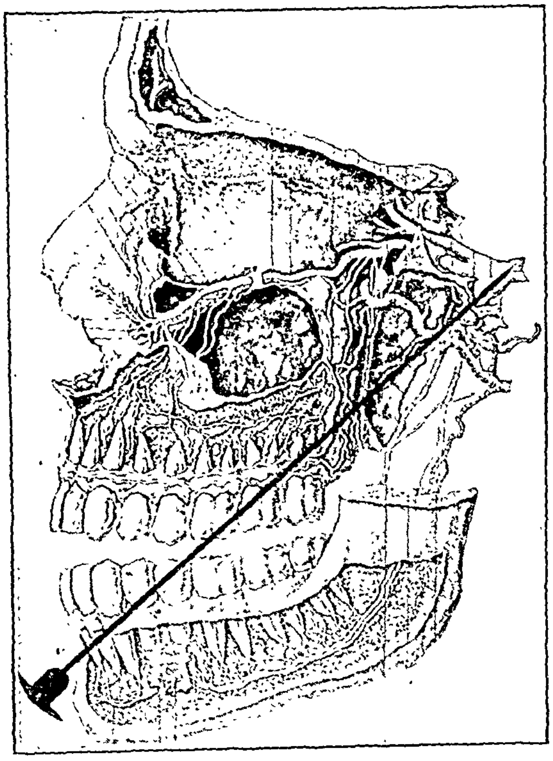

Fig. 5.—Schematic, showing needle point in sensory root.

> It is important not to inject more than a few drops of the alcohol at a time, and to wait at least two minutes for testing the anesthesia on the forehead before pushing in any more alcohol. As soon as total anesthesia develops over the forehead and eyeball, there is a possibility that the damage to the ganglion cells may be so great that the total anesthesia does not evaporate, as is usually the case, though in the majority of cases as much as 0.5 c.c. of alcohol may be further injected after total anesthesia appears, without risk of its being permanent. When a total of more than 1.5 c.c. has been injected, this risk is a very real one, and if total anesthesia still persists half an hour after the injection, the eyelids should be closed by rubber plaster and a pad and bandage, in order to prevent the risk of keratitis developing, which is certain to appear on the following day if total anesthesia is still present. If, however, sensation is returning in the first division and pressure on the eyeball can be felt definitely, then the risk is past. When, however, the anesthesia is still complete on the following day, then it is practically certain to persist for weeks or months and the eyelids should be sewn up, leaving a chink at either canthus for washing out the palpebral cavity with saline. So long as the lids are kept closed, keratitis will not develop, and even a certain degree of keratitis which had developed, previous to the sewing up of the lids, will clear up. I have been forced to have this treatment adopted in seven patients whose ganglion I had injected. The cure of the neuralgia is, however, certain and likely to be permanent, though my first case of injection of the ganglion dates back only four years.
>
> In many subjects it is possible to push the needle through the lips of the foramen ovale into the ganglion itself, though this is rarely necessary. A curious point, which I am unable to explain, is that after the ganglion injection, the anesthesia in the first division is more intense and more lasting than in the second or third divisions, a point which is peculiarly unfortunate, owing to its dependent keratitis.

I have incorporated this extensive quotation into my paper for two reasons: First, it clearly sets forth some essential facts regarding this procedure, and second, it embodies some conclusions with which I do not entirely agree. I do not agree, first, that the injection should begin at the lips of the foramen ovale and that it is rarely necessary to push the needle through the ganglion. This, in my opinion, is erroneous. The needle should not only be pushed through the ganglion but an attempt should be made to place the first 0.5 c.c. of the alcohol directly into the posterior root, injecting the remainder into the ganglion as the needle is withdrawn. Naturally if the alcohol is injected only at the lips of the foramen, the anesthesia in the first and second divisions would begin to fade away after a few minutes, because actually only the third division has been injected, the other two being temporarily affected by percolation of the injected fluid. If the patient is to have a permanent cure of the neuralgia, he must also be prepared to endure a more or less permanent anesthesia as well.

Secondly, I disagree with the suggestion that the eyelids should be sewed up. Never, never do that! If a neuroparalytic keratitis should occur, the eye must be suitably protected, and it should also have the benefit of daily cleansing with instillations of atropin and argyrol solutions.

The assertion that "so long as the lids are kept closed, keratitis will not develop" is also erroneous, keratitis often appearing during the first twenty-four hours, manifesting itself first as an epithelial exfoliation usually directly at the apex of the cornea, although I have seen it in the lower segment.

TECHNIC OF THE OPERATION

The technic should in the first place be strictly surgical with the patient lying supine and under a general anesthetic. I have the skin of the entire face on the side to be injected cleansed, first with benzin followed by iodin and after a few minutes with alcohol. I then study the contour of the face and head, getting a mental picture of the location of the foramen ovale (which is not by any means constant but varies in different individuals). The needle, which is 10 cm. long graduated up to 8 cm., is then with one deliberate thrust inserted into the sphenomaxillary fossa; at this time it is well to pass through the needle an obturator or stylet which serves several purposes: First, it extends a little beyond the point of the needle, rendering the needle point less sharp, thus limiting the chances of injury to blood vessels encountered. Secondly, it clears the lumen of the needle of any inpedimenta that may have been acquired during its passage through the cheek wall. Finally, it prevents obstruction of the needle during its further passage.

The needle is now advanced cautiously in the direction of the foramen as pictured in the mind of the operator, and if he is lucky, will often pass at the first thrust directly into the foramen without touching the bone at all. The operator will immediately recognize this fact by the sense of touch, if sufficient practice has been had on the cadaver. If bone is encountered, however, one must then ascertain the depth to which the needle has penetrated, and if this should be approximately 6 cm., the point is in the neighborhood of the foramen. If, on the other hand, it should be less than 6 cm., the point is above the foramen, and if more than 6 cm., the point is below the foramen. Gentle manipulation, with the topography well in mind, will usually place the point in the foramen without having to withdraw and reinsert the needle.

When one finds the needle in the foramen, it is well to pause and again study the contour of the face and head, not neglecting to slide the skin of the face upward on the needle where it has suffered slight depression or dimpling from the passage of the needle. This should show a penetration of about 6.5 cm. A firm hold on the needle is taken and it is advanced until the 8 cm. mark is almost reached or until a certain fibrous resistance is encountered, which indicates that the dura has been reached and consequently the insertion is too deep. In this case, the needle is slightly withdrawn, leaving the point as nearly as possible resting in the sensory root; the stylet is now withdrawn and the operator waits a moment, carefully observing whether either cerebrospinal fluid or blood should well up through the needle. In the former case, the point is within the dura and should be slightly withdrawn before the injection is made; in the latter case, the point is within the lumen of a blood vessel and the injection must not be attempted until the operator is absolutely sure that this position has been corrected, as very disastrous results have been reported from the injection of alcohol into a blood vessel, among them, gangrenous necrosis of the palatal bone with sequestrums. However, this is an unpardonable error and should never occur.

I always inject preliminary to the alcohol, 5 to 10 minims of a 0.5 per cent. solution of cocain or a 2 per cent. solution of procain. This is done for the purpose of inducing temporary anesthesia in the area supplied by the fifth nerve, in order that the patient may not suffer from the great burning pain caused by the action of the alcohol after recovery from the anesthetic. To complete the operation, 2 c.c. of 95 per cent. alcohol are now drawn into the syringe, half of which is injected in or near the posterior root, the remainder being slowly distributed throughout the ganglion as the needle is withdrawn.

In case a general anesthetic is not used, the only modification of this procedure is preliminary injection of a local anesthetic into the skin and subcutaneous tissues of the cheek and again when the point of the needle reaches a depth of 6 cm., waiting in each instance from five to ten minutes for full effect. In order to accomplish this the stylet will, of course, have to be removed temporarily, but must in all instances be reinserted before the needle is farther advanced.

In some instances, as stated, the needle will find the foramen with astonishing ease, while again one will have to grope for it patiently and persistently. The point of entrance is usually about 2 cm. above and external to the corner of the mouth. The needle should closely graze the alveolar process of the upper jaw, passing between this surface and the ramus of the lower jaw. With the patient supine and the head bent backward at an angle of about 30 degrees, the direction is almost perpendicular; but if the head is held erect, the direction is about 15 degrees upward but will vary in different subjects.

In old persons who have neither teeth nor alveolar process in the upper jaw, the locating of the foramen is exceedingly difficult but not by any means impossible.

The immediate results of a deep injection, as advocated in this paper, are anesthesia of the entire area supplied by the fifth nerve, which persists for a variable time and in variable degrees, and an analgesia which in the great majority of cases will be permanent.

REPORT OF CASES

Case 1.—A man, aged 23, was suffering from genuine unilateral neuralgia of the left side, which had existed for from one and one half to two years. The operation was classical; a few minims of procain solution in the skin and subcutaneous tissues produced perfect local anesthesia, and the needle passed through the cheek and sphenomaxillary fossa without pain When the inferior maxillary nerve was reached, sharp pain was complained of, which was almost immediately relieved by a few minims of procain. The needle was then advanced 1 cm., and when pain was complained of, procain was again injected; when the needle was advanced another 0.5 cm. and procain injected, the patient at once remarked that he had a strange feeling in the eye, face and tongue. One c.c. of alcohol was then injected without pain, and the patient was found to have complete anesthesia of cornea, skin and mucous membranes supplied by the fifth nerve. This patient developed a neuroparalytic ulcer in the lower temporal quadrant of the cornea, which persisted for weeks. He would not remain in the hospital, but was seen once a week for two months. When discharged, the corneal ulcer had healed with only a slight opacity, as the ulceration had been very superficial, apparently no deeper than the corneal epithelium, and gave him no trouble at all. When last seen, three months after injection, there was practically total anesthesia of the entire area supplied by the fifth nerve, and no return of "tic."

Case 2.—A woman in Dr. Horsley's service at the Memorial Hospital, Richmond, had been a victim of trigeminal neuralgia for years and had had numerous peripheral operations, including resections and nerve trunk injections. She complained that all of her injections had been exceedingly painful and of little benefit. She was suffering intensely when I first saw her, and would cry out if even a motion were made to touch her face. The entire distribution of the nerve was apparently involved, but the mandibular division seemed to be the most affected, this area being exquisitely sensitive. She would cry out if the floor were jarred or the bed brushed against, and, in short, presented a typical trigeminal neuralgia. Incidentally, she had become a morphin habitué. The injection was done under ether anesthesia, and the patient was seen the next morning sitting up eating breakfast, free from pain, and has remained so ever since (four years). Furthermore, she was freed from the morphin habit and returned to her home a very happy woman.

Case 3.—A woman, aged 30, of a highly neurasthenic type, had suffered from painful "tic" on the left side for years, with occasional attacks on the right side. Nasal examination revealed constant contact of both middle turbinates with the septum. This was corrected without relief. She then visited Sluder and had an alcohol injection in the sphenopalatine ganglion on the left side without relief. Previous to this she had had divulsion of the supra-orbital and of the mandibular through their respective foramina. In the latter part of November, 1914, the left ganglion was injected with 1 c.c. of 95 per cent. alcohol with immediate relief from pain lasting four months. She had total anesthesia of the entire area with abducent paralysis on the left side, the latter persisting through a second injection of 2 c.c. of alcohol four months after the first one. The relief from the second injection lasted about the same length of time, when severe pain recurred in the mandibular branch.

Case 4.—A woman, aged about 60 was brought into the hospital suffering from tic douloureux on both sides, with spasmodic "tic" involving the muscles of mastication on the right side, the pain on this side being very great. Her history was that of long-standing trigeminal disorder on both sides. The ganglion on each side had been extirpated some years before by Cushing with considerable relief, but not a complete cure. On the right side numerous peripheral operations had been done without relief. The stump of the posterior root of the right ganglion was injected with 2 c.c. of 95 per cent. alcohol under ether anesthesia, with prompt relief from both spasmodic and painful "tic," which lasted about two and one-half years. A second injection was made in this case about four months ago with only moderate relief from pain, but curiously enough we had this time a slight exfoliation of corneal epithelium which did not occur after the first injection.

Case 5.—A man who had had excruciating pain for years came into the clinic of Dr. H. B. Dechard of Dallas, Texas. An injection was done under local anesthesia, and was classical, the needle entering the ganglion at once. However, when the alcohol was injected, the patient was greatly nauseated, and complained of sudden deafness, dizziness, etc. The immediate results were total analgesia, total anesthesia and partial paralysis of the muscles of mastication which still persist (three years after operation). The only complication was a neuroparalytic keratitis, which ulcerated and did some damage to the eye, but from which the patient eventually recovered.

About this time my work was interrupted by a serious automobile accident which forced me to remain idle for two years. My sixth patient, therefore, was not seen until January of this year.

Case 6.—A woman was sent to me by Hillard Wood with a history of long-continued painful "tic," with many futile attempts at relief. The injection was done under ether anesthesia, and the relief was prompt and apparently permanent. She had neuroparalytic keratitis which ulcerated and had not healed at last report (three months after operation). She also had abducent paralysis.

Case 7.—A woman was injected, March 13, 1918, under ether anesthesia. Relief was prompt and apparently permanent. She had slight exfoliation of the corneal epithelium, but no ulceration.

Each of these patients had herpetic ulceration of the lips, tongue and buccal mucous membrane on the injected side, which invariably disappeared within two weeks. All of the patients complained in a greater or lesser degree of the various paresthesias and isolated spots of hyperesthesia originally described by Haertel.

ABSTRACT OF DISCUSSION

Dr. Hugh T. Patrick, Chicago: From the pictures I gather that Dr. Martin uses the method of Haertel, independently worked out by a New Orleans surgeon whose name I forget, in both instances for purposes of local anesthesia. To use the method for neuralgia was a second thought. Like all other methods of deep injection it is uncertain. Owing to marked differences in size and shape of the skull, the foramen may be very difficult to find, and one never knows just where the point of his needle is. I have never used the Haertel method because of the inherent dangers, although I think it might be the operation of choice when simpler and safer methods have failed. The Harris method of injecting the ganglion I have used successfully several times, though in some heads it is impossible. In my opinion we are not prepared to say that injection of the ganglion or of the sensory root cures trifacial neuralgia. Personally, I believe that it does not, though, of course, it may give relief for five years or more.

After making more than 1,000 injections in several hundred patients my opinion is that if the patient is relatively young and in good physical condition, the radical operation should be done, provided it be done by a high-class surgeon with experience in this operation. For the very old and for those with grave organic disease one of the injection methods is indicated.

Dr. Joseph C. Beck, Chicago: I would like to take issue with Dr. Patrick on his last remark, that there is a question of choice between the radical operation or injection. I should say, first try the injection, no matter what the condition is, and then if that fails do the radical operation, because we always have time for that. Dr. Martin certainly has had a great deal of experience in injection of the foramen ovale and speaks with more authority than I can. I have a record of forty-seven injections of the foramen ovale—that is forty-seven times, not forty-seven cases. Three injections were successful, and two were successful by the radical operation—one just the cutting of the sensory root—as recently recommended by Fraser.

In regard to the stylet, I use the Sluder needle, with a wire in it. In feeling for the foramen I depend on the flat plate at the base of the skull. These landmarks of the teeth for direction are all well enough but, as Dr. Patrick said, heads differ, and we must feel for the foramen at the external pterygoid plate close to the base of the skull. You must also consider the amount of fat there is on the face. Some people have 3 inches of fat on their face. The roentgen ray will give much information as to just how far the malar bone protrudes. The malar bone will give quite a lot of information as to how far you should go, and it is well to have a roentgenogram. I have never encountered any cerebrospinal fluid in any case that I injected. I have gotton a few drops of blood from the needle, and, of course, there was no injection made in those cases at that time. Nothing was said about the spilling of a large amount of fluid and the effect on the neighboring nerves. The sixth nerve is very close and I have seen paresis of the abducens follow that lasted for two months after the injection of alcohol for tic douloureux. I have tried the Harris method in three cases, but the point I would like to make is, that in a case where we fail with injection the operation Dr. C. H. Frazier recently described is the operation of choice.

Dr. H. H. Martin, Savannah, Ga.: I want to take exception to nearly everything that Dr. Patrick has said. His entire argument falls down when he admits that he has never done this operation, has not seen it done, and is unwilling to attempt it. There is only one way to learn to do the operation and that is to do it many times on the cadaver. You must do it and keep on doing it until you have acquired sufficient skill to know just where the needle point is at all times. Often the needle will slip into the foramen with the most astonishing ease; but sometimes you will have to grope for it. I have only treated nine cases and out of the nine all but two have remained free from pain for four years. If that is not a cure, what is? Unfortunately, I met with an automobile accident in 1915, and my work was interrupted for two years, which accounts for the hiatus in my case reports. In addition to the nine cases of genuine trifacial neuralgia I did a lot of injections in negro cases by paying them two dollars for the privilege. I also tried cocain injections into the ganglion for operating on alveolar abscesses and other local conditions, and in that way I got a whole lot of practice on living subjects. I think this operation is much more simple and safe than anything else that has been devised. I thank Dr. Patrick for telling me whose method I use, for I did not know, Haertel originally entered through the mouth, but later adopted the technic described in this paper. I think it is much more satisfactory to use a needle with the markings on the needle rather than on the slide. I use a needle of sufficient diameter that the markings can be made with safety. I use 2 c.c. of alcohol, diffusing a portion in and around the sensory root of the nerve and the balance in the corpus of the ganglion as the needle is withdrawn.

Military Medicine and Surgery

THE ROENTGENOLOGIC STUDY OF EMPYEMA CAVITIES

FRANKLIN A. STEVENS, M.D. (Boston)
Lieutenant, M. C., U. S. Army
BILTMORE, N. C.

The surgical treatment of chronic empyema cavities and sinuses should be guided by two laboratory methods: The first, which is relatively the most important, is the bacteriologic examination of the discharge, and the second is a careful roentgenologic study of the existing pneumothorax. A proper correlation of these findings is necessary, however, to obtain satisfactory results; even though the bacteriologic control guides the surgeon in the correct use of neutral solution of chlorinated soda (Dakin's solution) and indicates that the cavity is sufficiently sterile either to allow healing or to permit a radical operation, the knowledge obtained by means of the roentgen ray is an absolute essential. It not only detects abnormalities in the lung tissue, but also demonstrates the size, shape and location of the draining cavity and affords some knowledge of the walls that surround it. This can be accomplished, however, only by a carefully standardized technic which is an accurate means of diagnosis and is at no time detrimental to the patient.

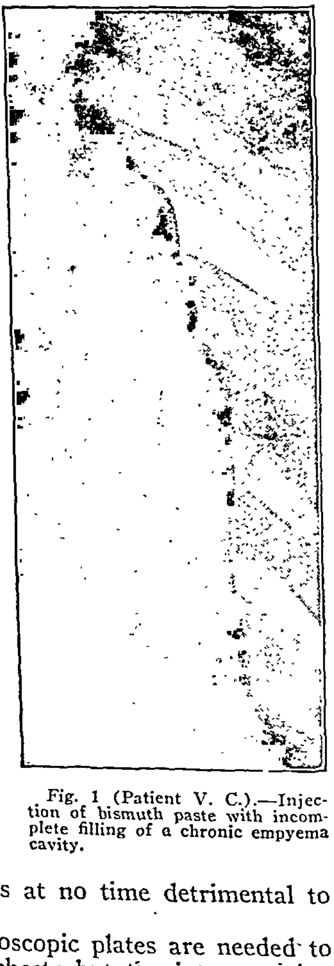

Fig. 1 (Patient V. C.).—Injection of bismuth paste with incomplete filling of a chronic empyema cavity.

It is obvious that stereoscopic plates are needed to locate points within the chest; but the interpretation of the various densities in a draining empyema is a far more difficult problem. Simple large cavities bounded by lung and axillary thoracic wall are easily outlined because the bronchi and their branches, thickened by long continued inflammation, can be sharply traced to the lung border. In cavities of bizarre shape with ramifications between and around the lobes, the delineation is much more difficult and can be accomplished only by completely filling the cavity with some substance opaque to the roentgen ray. A probe may be inserted and either observed in position or withdrawn and measured to estimate the depth of the sinus, but lateral measurements cannot easily be demonstrated in this way. The most practical method is the introduction of either a solution or paste containing some metal or alkaline earth, either as a salt or as a finely divided suspension. Various combinations of these salts and excipients have been used and their technical defects studied.

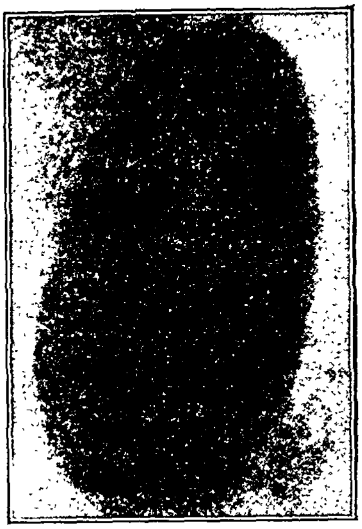

Fig. 2 (Patient V. C.).—Cavity filled with thorium nitrate solution, showing the exact size.

There is no one method that satisfies every requirement. Combinations of petrolatum and waxes as a carrying medium, especially when employed with bismuth, offer such mechanical disadvantages and are attended with such danger to the patient that they should be abandoned for diagnostic purposes. Very frequently the extent and gravity of secondary operations are not indicated because the roentgen-ray injections show the cavities incompletely outlined. Even before this stage of the treatment, the partial filling of the cavity erroneously leads the surgeon to believe that the lung is expanding. This incomplete filling is due to the stiffness of the paste which, as it cools, prevents the escape of air from the deeper recesses of the cavity. In the warm semiliquid state the mass fills only the most dependent part, and if the patient is placed on the well side during the process of injection, only that part of the cavity lying near the vertebral column is filled. Another important objection to the use of bismuth paste is the difficulty encountered in removing it when tortuous sinuses and pockets have been injected, and it is in these cases particularly that chronic bismuth poisoning so frequently results. The injection of even a moderately heavy paste also requires so much pressure that it alters the outline of the cavity, causes pain, and probably impedes the reparative processes. These faults are remedied by the use of fluid mediums.

The solutions in common use are potassium iodid and thorium nitrate. While they are advantageous so far as the filling of the entire sinus or cavity is concerned, alarming results often occur from absorption when they are used in large cavities. Potassium iodid, although easily obtained and prepared, is very irritating, and the pain experienced by the patients prohibits its routine use. Thorium nitrate does not produce such a reaction; but even if chemically pure, chills, fever and hematuria are frequently observed after large quantities have been used. As a result of these observations, it is evident that the proper material should be either a suspension of an insoluble substance or a colloid of some metal. Colloids are frequently difficult to prepare and lack certain advantages to be mentioned later. Although bismuth subnitrate is followed by harmful effects if left in the cavity indefinitely, these are eliminated if it can be removed promptly. To accomplish this end its use can be permitted only in suspension in a liquid medium of sufficient body to maintain its homogeneity for a reasonable length of time. Cottonseed oil, aside from its cheapness, has all these requisite qualities, and a sterile mixture of this oil with 20 per cent. bismuth subnitrate and 3 per cent. powdered acacia is found to meet all requirements.

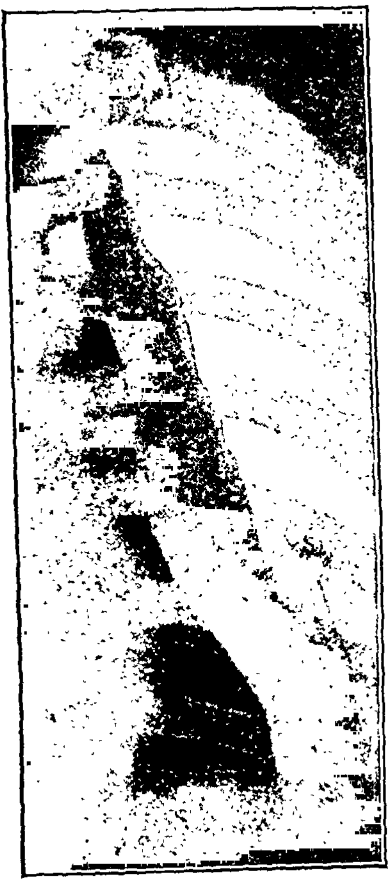

Fig. 3 (Patient M. R. S.).—Bismuth paste injection only partially outlining the cavity.

The filling of an empyema cavity must be done with a knowledge of its general direction, as it is then possible to place the patient with the deepest point of the cavity in the most dependent position. The warm suspension of bismuth and oil is drawn into a sterile syringe and, without touching the wound at any time, is allowed to flow slowly down the walls of the cavity. This effects the gradual displacement of the air from the deeper parts. Since most of the resections have been done posteriorly, the patient is laid across the table with his head and body hanging down, supported by an attendant. The quantity is recorded and more is allowed to run in until air bubbles no longer escape and breathing causes an overflow. Plates taken at this time show the cavity well filled, but the opening through the chest wall is not demonstrated. To overcome this, the wound is tightly packed with narrow strips of gauze previously dipped in bismuth petrolatum paste and sterilized. The patient is carefully raised on the table face down, and the exposures can then be made without the loss of the mixture; the resulting shadow corresponds exactly to the cavity. As far as possible, all patients should be taken in the same position, so that the operator may become accustomed to the same chest markings. The head is turned to the left with the right cheek down; the hands are placed under the thighs with the elbows extending just off the edge of the table. In order that the cavity may not be abnormally distended, it is important that no pressure be used in the injection. Immediately after the first pair of plates is exposed, the tampon is removed, and when the bulk of the bismuth suspension has drained out, a second pair is taken with a thin film of bismuth still adherent over the cavity. This procedure gives an exact quantitative measurement of the contents, and in addition allows the study of the cavity as it exists when not injected. The study of the plates after these injections shows that the shadow is nearly as dense as that obtained with bismuth paste; but because of this density it is difficult to estimate the distance between the lung and the parietal pleura. With the bismuth oil injection, however, this disadvantage is overcome, because sufficient bismuth adheres to the walls in the second pair of plates so that an exact picture of the cavity in all its dimensions can be obtained.

Many injections were made with paste during a period of three months in the treatment of more than 100 cases. On closely viewing the plates at a later time it was discovered that many of them were very misleading. Most of the cavities had apparently decreased very much in size, but on careful examination the walls of the sinuses could be traced some distance beyond the shadow of the injected bismuth paste. Because of this discrepancy they were again roentgenographed with thorium, and as was expected, it was found that it was impossible to obtain a correct outline unless the cavities were completely filled. In practically every case in which the cavity was of any size or depth, the cubic contents were far in excess of that anticipated, and the roentgenograms even showed that it was unsafe to attempt to estimate the size and shape of these wounds unless they were completely filled. Some had been reported as "partially injected pneumothoraces," evidence which was of little value to the surgeon.

Figures 1 and 2 were made at intervals of four days and illustrate the marked discrepancy between a paste and liquid medium. The patient had a chill with marked hematuria for a few days following because of the thorium employed, and it was for this reason that an oil-bismuth suspension was substituted in all subsequent work.

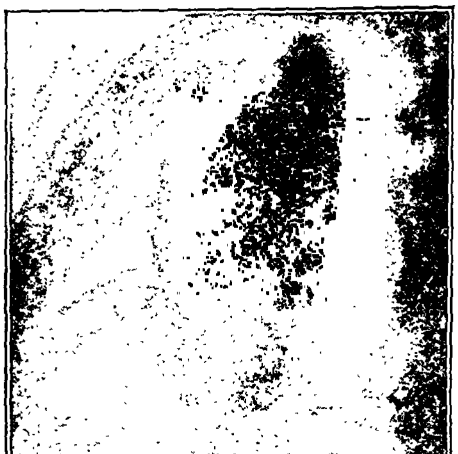

Fig. 4 (Patient M. R. S.).—Cavity completely outlined with bismuth oil injection.

Figures 3, 4 and 5 were taken in a second case at an interval of four days. The paste has been forced along the vertebral portion of the cavity, and in the upper part there is a large irregularly shaped accumulation of air that has not escaped. The bismuth oil injection completely fills the wound, revealing a cavity so shallow that one can see through it with ease. In Figure 5, taken immediately after the oil was removed, the outline is still very definite, and stereoscopically the lung and pleura are found lying in close approximation.

There is no retention. With the knowledge that 30 c.c. of the mixture were required in this injection, a very definite idea of such a cavity is obtained.

An attempt was made to discover whether the presence of this fluid, even under no pressure, caused a distortion. A series of plates was made in the same manner as the three just mentioned. Those made with paste were obviously incorrect. On observing the sinuses filled with oil and bismuth it was noted that although they conformed to the curvature of the chest wall, many were abnormally far from the ribs. This is frequently observed in chests with a very thick parietal pleura. The third pair in each of the series illustrated the collapsed sinus after the oil had escaped. There was sufficient bismuth still adherent to give a definite outline, and the decrease in size was evident, demonstrating the slight distention of the cavity with the injected mass in place. Difficulty was experienced in securing photographs taken in the same position. Since the ventral prone position has been used in the oil injection, it was not always possible to select similar positions from among the previously injected bismuth plates.

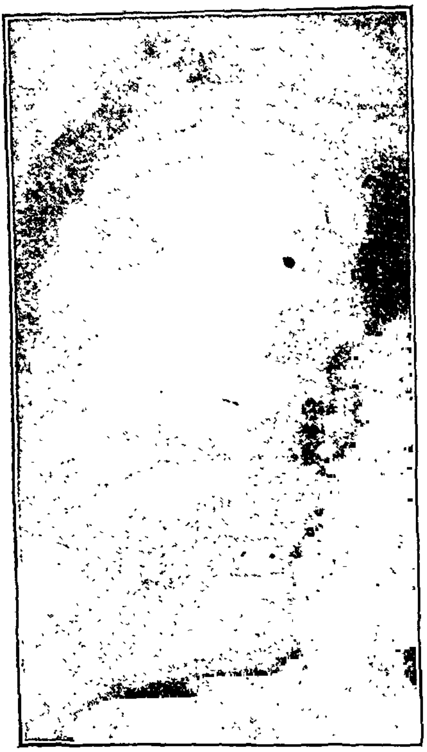

Fig. 5 (Patient M. R. S.).—Cavity sharply outlined after the oil and bismuth have escaped.

Tax on Child Labor Suggested.—That an exorbitant tax should be levied on merchandise or any production of child labor as the only logical method of eliminating the evil was the chief point brought out in a rousing address by Owen R. Lovejoy, general secretary of the National Child Labor Commission, at the opening session of the fifty-first annual meeting of the Maryland State Teachers' Association, which convened, November 29, in Baltimore; while a federal, centralized educational system discussed by Dr. William Chandler Bagley, professor of education at the Teachers' College, Columbia University, also struck a responsive note among the hundreds of educators present. In view of the fact that the results of the recent selective draft classification and examinations disclosed that 750,000 persons, all male, were illiterate, Dr. Lovejoy laid stress on the fact that child labor is largely responsible for that deplorable condition. These figures do not include the illiterate females in this country. Although the issue has not yet been adopted by the association, Dr. Rozell Berryman, Baltimore, treasurer, said that it conformed with the unanimous view of the teachers, and that it will ultimately be adopted in the resolutions. This means that a concerted effort will be made to that end in having such tariffs and taxes apply. A national system of education as is in vogue in England and France was strongly advocated by Dr. Bagley, who declared that only in that way could any comprehensive and effective system be evolved.

THE EAR IN "STUNT" FLYING*

LEWIS FISHER, M.D. (Philadelphia)
Major, M. C., U. S. Army
AND
H. W. LYMAN, M.D. (St. Louis)
Captain, M. C., U. S. Army
MINEOLA, L. I., N. Y.

Crashes that occur during "stunt" flying are usually the result of something having gone wrong with the pilot. Hence, it is a pertinent matter for medical investigation. Just what this something is, is not always clear. Poor judgment, a sense of bravado, carelessness, "stunting" at low altitudes, and sudden faintness are among the reasons generally offered in explanation of these accidents. Direct testimony of the pilot is not always available, since many of the crashes result fatally. Neither are pilots who have crashed and survived always able to give a clear and concise account or analysis of the causes of the accident.

Underlying them all, however, there runs a story of momentary loss of faculties, resulting in a manipulation of controls without deliberate judgment. Most accounts of crashes read, "The pilot went into a tail spin and failed to come out." The story of Lieut. J. M. M. is quite typical of those collected by this department. While flying, he went into a tail spin. This produced such overpowering dizziness that, not knowing what he was doing or why, he grabbed the "joy stick" and pushed it forcibly over and threw himself into another tail spin in the opposite direction. Before he could come out of this he crashed.

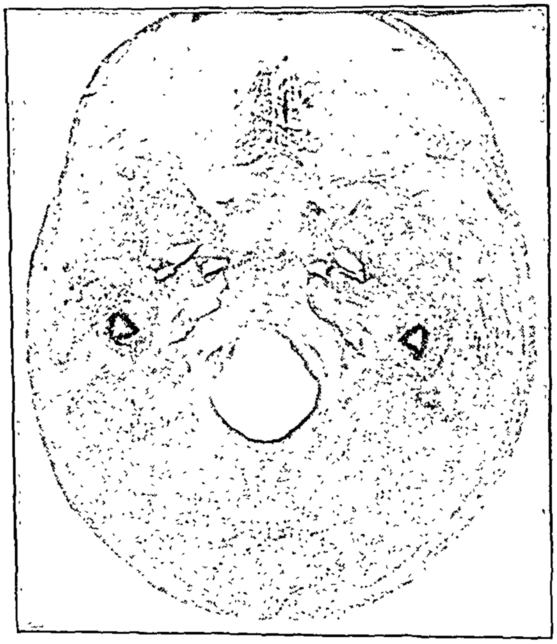

Fig. 1.—Base of skull from above, showing semicircular canals in situ.

So many of the accounts of crashes given by pilots who do survive emphasize dizziness (or vertigo) that the organ responsible for dizziness when an individual is whirled around, namely, the ear, was necessarily made the subject of investigation by the otologic department of the Medical Research Laboratory at Mineola. Experiments which involved the whirling of individuals point conclusively to the fact that stunt flying is essentially an ear problem.

---

* From the Department of Otology, Medical Research Laboratory, Hazelhurst Field, Mineola.

By visualizing the position of the pilot as he is whirled in the various stunt evolutions, we found that by reproducing a similar whirling in the apparatus it was possible to simulate all the subjective effects of the actual stunt.

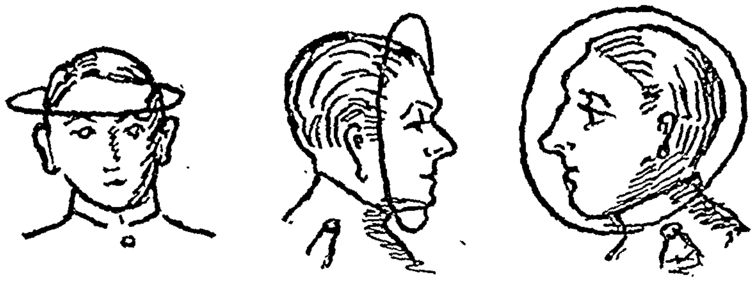

Fig. 2.—Three cardinal planes of vertigo: horizontal, frontal and sagittal.

Lieut. J. F. D. (150 hours in the air) was placed in a certain position in the apparatus and whirled. He volunteered the information that his sensations were identical with those experienced when coming out of a tail spin. When placed in the apparatus in a certain different position and whirled, he stated that his sensations were those experienced when coming out of a tight spiral. Lieut. W. E. R., an experienced pilot, when placed in the apparatus in the same position as Lieut. D.'s first experiment, made the statement that his sensations were identical with those of his predecessor, saying, "That is exactly like coming out of a tail spin." When placed in another position and whirled, he said, "Now I feel like coming out of a loop." These facts were confirmed by similar experiments on other aviators.

Since being whirled in an aeroplane produces effects identical with those resulting from being whirled in a laboratory device, such as the turning chair, or other forms of apparatus designed for that purpose, we are furnished with an accurate and convenient means of studying the various vertigo effects of ear stimulation produced by evolutions in the air, and the deductions derived from this experimental stimulation are true and applicable to stunt flying. The facts gleaned were so exactly in accordance with our knowledge of the ear as a "motion-sensing mechanism" that they were simply corroborative of certain well known otologic principles. Now what are these established facts or principles?

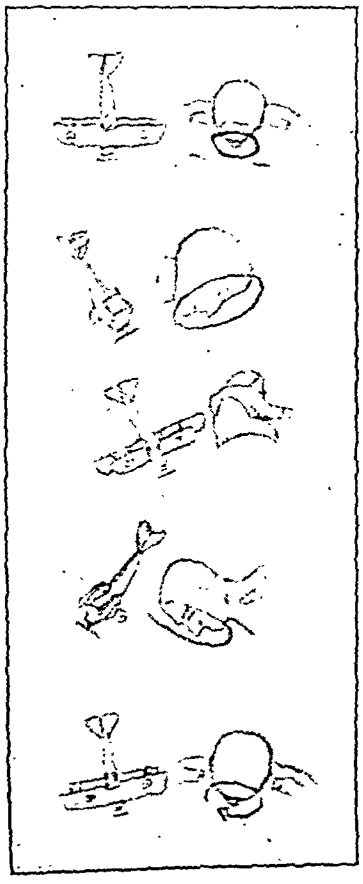

Fig. 3.—Spinning nose dive.

1. In each ear we have three semicircular tubes, or canals, containing fluid, so placed that they are at right angles with one another (Fig. 1). Because of this arrangement, no change of position of the individual is possible without producing some movement of fluid in one or more of the canals. Movement of the fluid in these canals sends messages to the brain which are there interpreted as body movement. Hence, the ears constitute the motion-sensing organs of the body.

2. When an individual is whirled, be it in the laboratory or in an aeroplane, there is produced a circulation of this fluid in certain definite canals and planes. Now, if the turning is suddenly altered or stopped, or if the aeroplane comes out of a rotating maneuver, the fluid in the canals continues to move in its former plane by sheer force of its momentum. The circulation of the fluid by momentum is interpreted by the brain as body movement; but not being in accordance with fact, the body having ceased to revolve, it constitutes vertigo or dizziness, and is disturbing to the individual.

Labyrinthine vertigo, therefore, is a false sensation of motion similar to the visual illusion of motion observed when one is watching a moving train from the window of a stationary coach, both being unavoidable phenomena of normal special sense mechanisms which, however, the subject easily learns to disregard.

One must not fall into the error, however, of thinking that the lack of a normal ear mechanism would be advantageous to the flier, because of the immunity to vertigo which this condition would confer. The absence of such an essential organ as a motion-perceiving apparatus is too great a handicap to the man traveling in an "air medium" to justify him even in thinking for a moment that he could dispense with it for the sole benefit of a vertigo immunity, especially since the normal individual can acquire such an immunity without much difficulty.

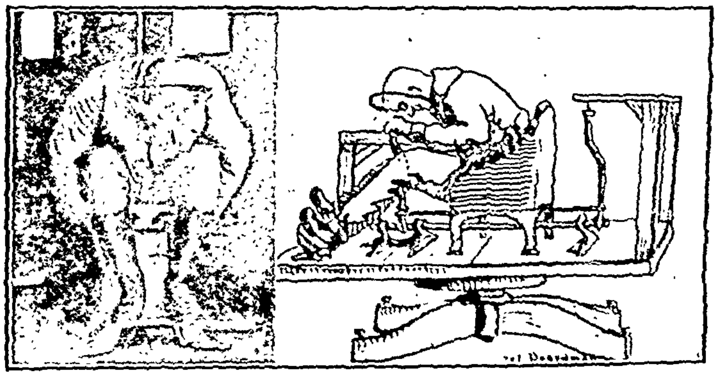

Fig. 4.—Position in turning chair to simulate spinning nose dive.

VERTIGO EFFECTS OF EAR STIMULATION LEARNED IN THE AIR

1. There are three cardinal planes of vertigo: horizontal, frontal and sagittal (Fig. 2).

2. A sense of being turned in a horizontal plane—horizontal vertigo—is less disturbing than a sense of being whirled in a vertical plane—vertical vertigo. Each semicircular canal, if stimulated, produces a vertigo in its own plane. Therefore, with the individual in an upright position, stimulation of the horizontal canal is much less disturbing than stimulation of the vertical canals.

3. When a disturbing or disabling vertigo is induced in the vertical semicircular canals, the effects can be greatly ameliorated by bringing the vertical canals in a horizontal position or plane, which can readily be done by bringing the head forward.

4. All types of vertigo, no matter how induced, are made less and less disturbing by continual repetition.

PRACTICAL APPLICATION OF VERTIGO STUDY TO STUNT FLYING

Let us consider how the knowledge of the various effects of vertigo gained in the laboratory can be correlated and applied to various stunts.

Spinning Nose Dive.—In this maneuver, the aviator, face downward, is whirled about an axis with his head and body practically parallel to the ground, as shown in Figure 3. In this position there is a stimulation of the vertical semicircular canals in a frontal plane, corresponding to turning in the chair in the position shown in Figure 4. When he "comes out" of the spin, the plane of vertigo which until now has been parallel to the ground becomes vertical in a frontal plane, that is, from side to side, so that instead of feeling that he is turning horizontally he feels that he is whirling in an up and down plane. This being very disturbing, he is apt to lose himself momentarily and attempt to correct this illusionary movement and so throw himself into another tail spin in the opposite direction. When the same experience is carried out in the chair, that is, when he is turning with his head forward simulating his position during the tail spin, and attempts to sit erect, he similarly changes the horizontal vertigo, with which he started, into a sensation of whirling in an up and down plane. In attempting to correct this false impression, he throws his body to one side or the other with such violence that unless caught by the examiner he would fall to the floor. It is easy to imagine what havoc would be raised with the controls of an aeroplane under similar conditions. The obvious remedy in both cases is to keep the head down as it was in the beginning so that the vertigo remains in the horizontal plane.

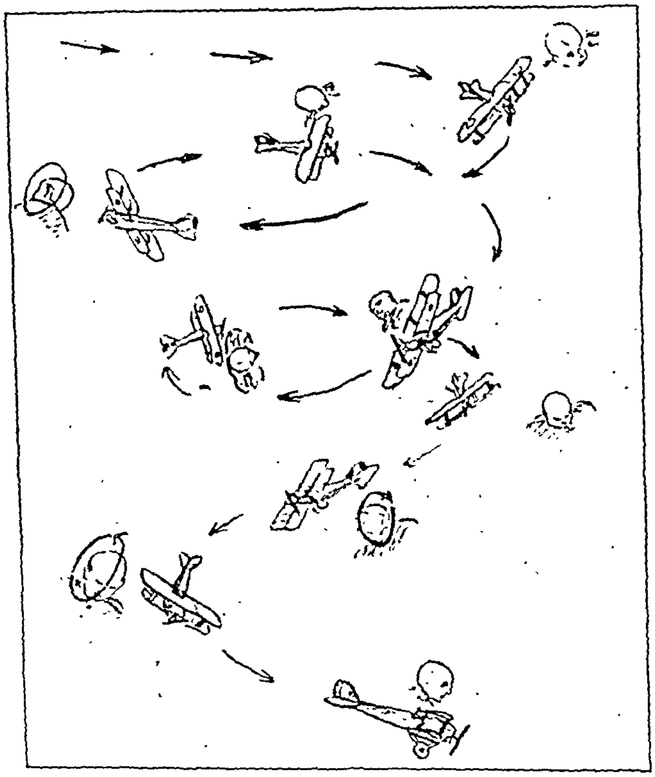

Fig. 5.—Tight spiral.

Tight Spiral.—In this maneuver (Fig. 5) the aviator is whirled about an axis with his head and body practically parallel with the ground but facing the horizon. The stimulation occurs in the vertical canals but in a plane practically parallel with the ground as long as the spiral lasts. When he comes out, however, the plane of vertigo, horizontal until now, becomes vertical in a sagittal (from before backward) plane, so that he feels himself pitching forward or backward and may again meet disaster in attempting to correct for this illusion.

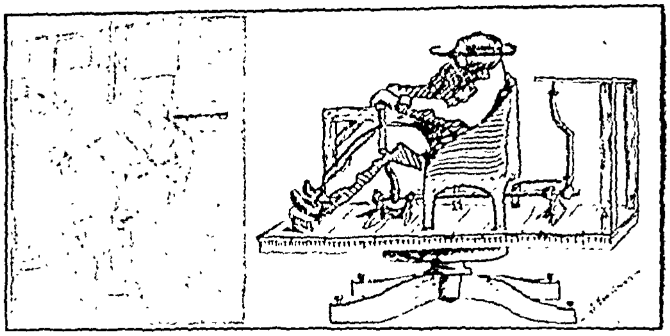

Fig. 6.—Position in turning chair to simulate tight spiral.

In the turning chair this maneuver can be simulated by turning the individual with his head sharply inclined over the shoulder (Fig. 6).

The obvious remedy for the aviator in this case is to tilt his head sharply to one side when coming out of the spiral, since by so doing he will prevent the vertigo from assuming an up and down whirl.

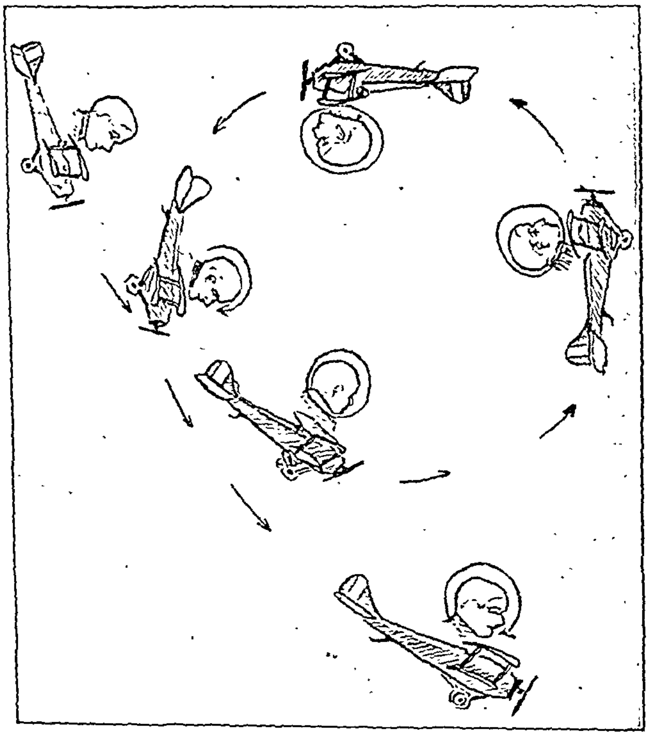

Fig. 7.—Loop.

Loop.—In this stunt, as shown in Figure 7, the vertical canals are stimulated in the sagittal plane (as in the spiral) but to a lesser degree. The correction is accomplished by tilting the head sharply over one shoulder (the position shown in Figure 6).

Immelmann Turn.—In this evolution, as shown in Figure 8, we have a compound maneuver. During the first or loop portion, the vertical canals are stimulated in the sagittal plane, followed in the second part by a stimulation of the vertical canals in the frontal plane. The effect of the first portion is lost during the remainder of the stunt, so that on emerging the aviator has only to deal with the vertigo induced by the last part, namely, the vertigo on the frontal plane. The obvious correction is to throw the head forward while "coming out." In a similar manner the vertigo induced by the "barrel roll," "falling leaf," "wing over," and other maneuvers can be readily analyzed.

It is, of course, true that the experienced stunt flier is not, as a rule, upset by vertigo induced by these stunts because of the many hours of practice he has had; but no matter how well trained and experienced he may be, he may occasionally find himself, especially in actual combat, doing whirling in a greater amount and at a greater rate of speed than his training has prepared him for, and an understanding of these principles might be the means of saving his life. As a matter of fact, stunt fliers develop instinctively certain maneuvers that neutralize the disabling effects of vertigo; thus one flier found by practical experience that by leaning as far forward as possible, so that his head was practically inverted, a tail spin gave him practically no disabling vertigo. Another found that going into a straight nose dive immediately following a tail spin saved him from any uncomfortable dizziness.

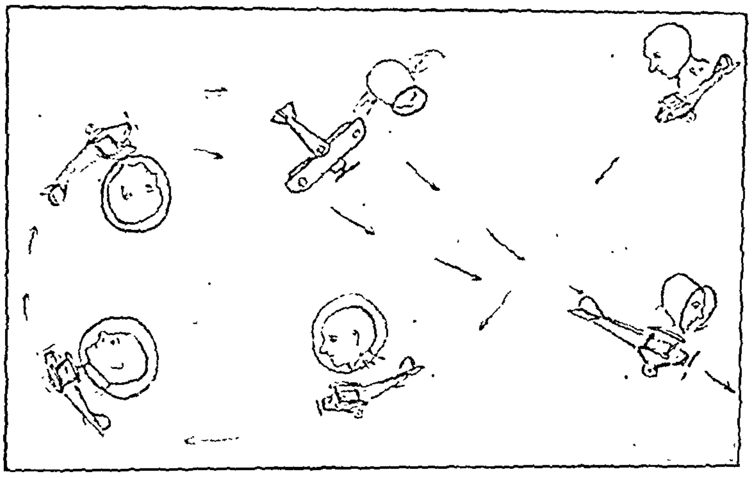

Fig. 8.—Immelmann turn. The circles indicate the plane of vertigo —sagittal first, then frontal.

These fliers have instinctively adopted means which at all times kept the vertigo in a horizontal plane—procedures based on sound otologic principles. Experienced aviators, on being put through the various stunts in the laboratory, when shown how easily the effects of vertigo are neutralized by certain changes in the position of the head, are of the unanimous opinion that such knowledge is of the greatest practical value, especially in stunting. It is obvious that to the less experienced this knowledge is of even greater importance.

The greatest usefulness of the knowledge that stunting is an ear problem lies in the fact that the flier may be educated to disregard the vertigo effects of his stunts in the laboratory instead of among the clouds, and without danger acquire a tolerance to evolutions to a degree impossible in the air. This can be accomplished by the use of an otologic apparatus known as the orientator. In its construction it is like the cockpit of an aeroplane suspended in concentric rings, after the manner of a ship's compass. The movements (or changes of position) which are possible in all directions except actual forward progression are governed by the individual seated in the machine, using a set of controls resembling those of an aeroplane. Strapped in this machine, he is enabled to execute any evolution, such as the loop, spiral, etc., at any desired speed for any number of turns and thus acquire in absolute safety a tolerance for the disturbing effects of vertigo induced by these evolutions, instead of acquiring this tolerance and knowledge by actual flying with its consequent crashes and possible loss of life. In addition, it will enable him to adapt himself to new and most unusual conditions. He will learn to orientate himself in new and rapidly changing positions of the body, and to perform properly the complicated acts necessary to control an aeroplane while flying with his head down, etc., which entails an entirely reversed relation to external objects, a condition in itself most disturbing and pregnant with possibilities of disaster.

STATIC DEFECTS OF THE FEET

A METHOD OF ACCURATE DIAGNOSIS AND A TREATMENT OF PROVED VALUE IN THE ARMY

EDWARD A. RICH, M.D.
Major, M. C., U. S. Army; Supervising Orthopedic Surgeon
WASHINGTON, D. C.

The underlying principle in all satisfactory treatment of the common static defects of the feet is that of restoring weight-bearing to those parts of the feet to which weight-bearing naturally belongs. All other forms of treatment of the longitudinal and transverse arch defects, all treatments of foot pronations or ankle valgus and the neuralgias of the forefoot that do not rigorously enforce this principle, are merely forms of treatment that support or palliate. Real cures of the static defects depend basically on establishment of the principle, first by artificial, then by natural, means.

There are two modes of approach that can be made use of to reestablish permanently the normal foot functions and the enforced use of the normal weight-bearing areas. First, there are the surgical and mechanical measures which in a valuable way make use of mechanics and force at efforts of reconstruction. These various procedures, valuable and important as they may be in civil practice, have little place in the present discussion. Early in the war, official orders rightly removed the knife from the hand of the orthopedic surgeon in the training camp. Second, there is that mode of approach which, recognizing the abnormality of the foot, determines on shoe alterations intended either to correct the statics of wrong weight-bearing or to render the normal shoe "abnormal" to compensate for the foot abnormality. The latter method is merely the forgotten aims of the old-fashioned horseshoer or the lost arts of the obsolete shoemaker. Further, several of the static foot defects, such as talipes valgus, are congenital affairs that tend to yield toward the normal on the application of the correct shoe mechanics. This paper is an attempt to emphasize the latter therapeutic phase.

To look at this mode of approach in a popular way: A certain shoe, properly selected, can be considered a normal covering for a normal foot. If a foot, however, is deformed, in the sense of being statically or organically abnormal, a standard or stock shoe does not "make a fit." *An abnormal foot demands an abnormal or nonstandard shoe.* Self-evident as the fact is, people have been crowding abnormal metatarsal defects, flat feet, cavus and pronated feet into normal store shoes. It is the same system as is the use of store spectacles or as would be the use of stock false teeth.

It does not seem feasible to revive shoemaking from individual lasts. However, to meet the great demand, the stock shoe has been a matter of long and careful study, with a view of remodeling. Civilian orthopedic surgeons and military boards have long given the matter of shoe alterations diligent attention, until today it can truthfully be said that the proper stock shoe can be so altered in its construction that it can be made to compensate for almost every abnormality common to the static defect.

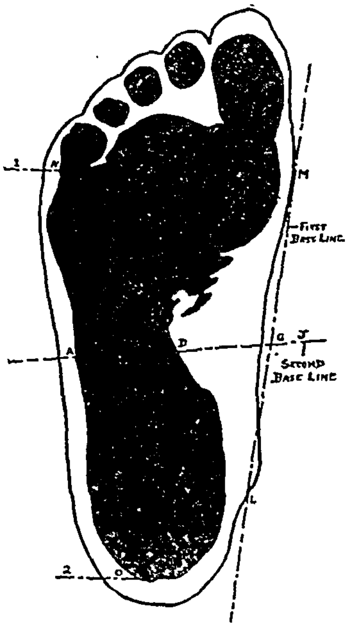

Fig. 1.—Pedograph of normal foot: Normal impression of weight-bearing area surrounded by contour line of the upper foot. First standard base line (LM) connects a fixed point posterior to the inner malleolus (L), and the metatarsal-phalangeal prominence (M). Second standard base line (AG) is drawn midway between Planes 1 and 2 and at right angles to the axis of the foot. Supplemental data: Feiss line, one-half inch; normal subcutaneous fat. This and the following illustrations were prepared by the Anatomical Art Department of the Army Medical Museum.

ACCURATE DIAGNOSES OF STATIC FOOT DEFECTS

The diagnosis of the static foot defects has always been largely made by guess. Diagnostic aids have not been commonly sought or encouraged. Many surgeons, uninterested in the foot subjects, have jumped at conclusions from mere inspection, with the usual result that treatments applied have been misfits. To diagnose and classify the foot defects without graphic aids is exactly on a par with the attempt at diagnosis and classification of the chest derangements without a stethoscope.

It is a lamentable fact that great masses of soldiers appearing in military orthopedic clinics showing by pedograph an ankle valgus, popularly termed pronated foot, prove on accurate test to have cavus with often abnormally high longitudinal arches; but their histories show often that previous civilian treatment had for its aim the restoration of a fallen arch. There seems to be a vague misunderstanding of the characteristics of the static foot entities.

PEDOGRAPH AND SCAPHOID SCALE

Our two infallible aids in diagnosis are the pedograph and the arch scale for the scaphoid. The two are supplemental; neither is of much value of itself.

The pedograph is merely an imprint on paper of the weight-bearing surface of the feet, surrounded by a pencil mark of the contour of the upper foot (Fig. 1). The pencil so describing this contour line is aways held perpendicularly to the drawing paper (Fig 2). This *impression of the weight-bearing areas of the feet,* made in the standing position, with the weight equally distributed on the two feet, can be made in many ways. It can be taken with ink in the usual manner for finger prints. But by far the better way is to use the ingredients of ink in two separate solutions, first coating the plantar surface of the feet with an iron solution that scarcely stains the skin; making the impression (drawing in the foot contour), and then coating the impression with tannic acid, turning it in a few moments to a jet black. The solutions commonly in use are:

Iron Solution	
Tincture of ferric chlorid	45
Glycerin	5
Commercial alcohol	50

Tannic Acid Solution	
Tannic acid by weight	10
Commercial alcohol	90

The foot impression portrays in an unmistakable way several general facts other than those pertaining to the foot itself. There are portrayed general constitutional and assimilative data, indications of character of a positive and negative nature, and more important unerring lateral lines bespeaking station, motor disturbances and ataxias (Fig. 3).

The addition of two straight lines to the pedograph makes its interpretation very simple. First is the first base line (*Fig. 1* LM), drawn with a ruler along the inner foot contour, connecting the point L or that position representing the point on the contour line immediately posterior to the inner malleolus, and the point M, a position on the same contour line registering the prominence of the metatarsal-great toe joint. (In the case of gross enlargements of this joint, allowance is made and the point M is assumed within the contour line.)

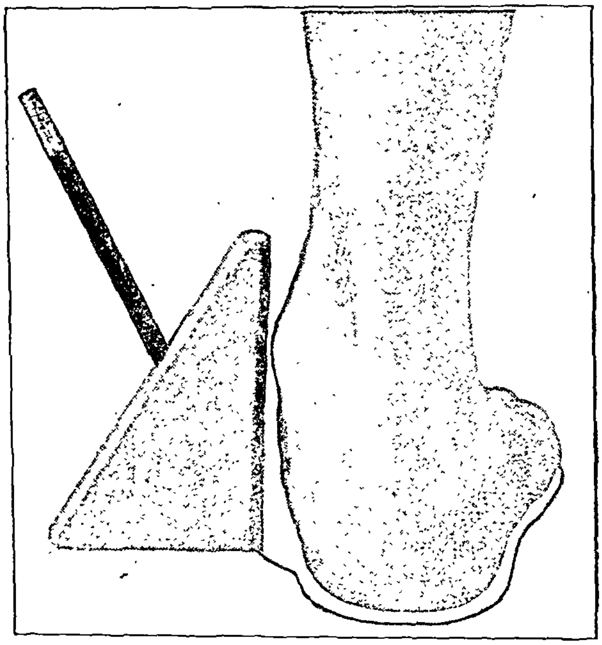

Fig. 2.—Perpendicularly drawn contour line of upper foot. "Travis block" is serviceable in maintaining a perpendicular while describing the contour line.

The next line added is the second base line. This line, AJ, is drawn at right angles to the axis of the foot, and in a plane half the distance from the base of the little toe (N) to the extension of the heel impression (O). The two base lines intersect at G.

SCAPHOID SCALE

The supplemental data for the proper interpretation of the pedograph pertain to the findings as to the actual height, by measurements of the lateral arch, as determined by the position of the lower border of the inner surface of the scaphoid bone. A line, sometimes called Feiss' line, is mapped out with a thin straight-edge, preferably a short machinist's rule, connecting the posterior inferior aspect of the internal malleolus and the distal end of the first metatarsal, plantar surface (Figs. 4 and 5). The scaphoid, which will be remembered as the keystone of the lateral arch of the foot, is found easily by continuing directly downward in the front line of the shin to a point in front of the inner malleolus. The lower rounded border of the scaphoid bone is carefully described by a mark on the skin while the patient stands bearing weight equally on the two feet. In normal feet this point on the scaphoid is about one-half inch below the line described. In all cases of cavus this point is found above the normal position, and is often to be found above the mapped outline. While in flatfoot, fallen longitudinal arches, the point may be 1 inch or 1½ inches below the line. When found, the position of the point on the scaphoid is thus placed on a corner of the pedograph: Feiss, ⅞; Feiss, 0; Feiss, —¼, etc.

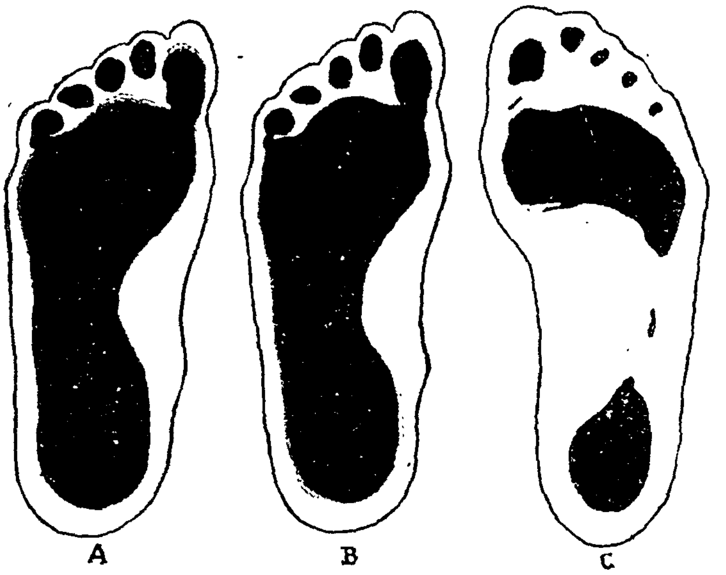

Fig. 3.—Postural and assimilative data recorded by pedograph: *A,* posture in alcoholic intoxication: forefoot blur; *B,* posture in ataxias: blur on lateral aspects of impression; *C,* impression in extreme emaciation: normal arch.

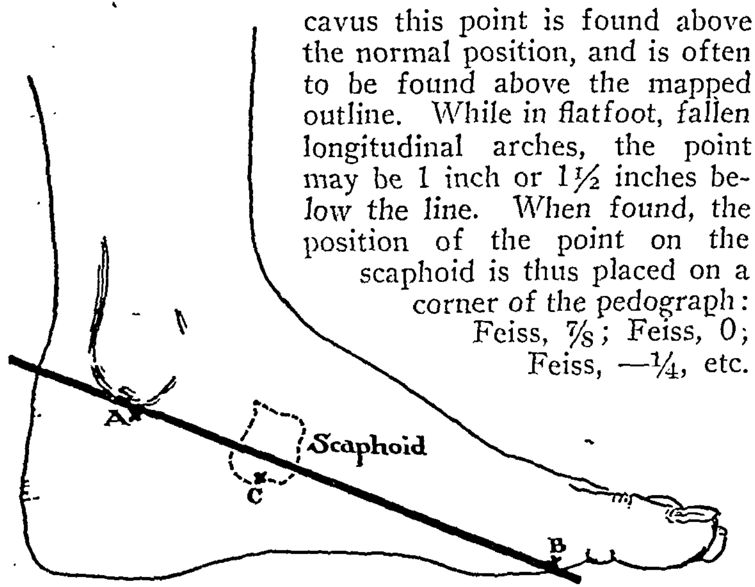

Fig. 4.—Arch scale for the height of scaphoid; sometimes the line is called the Feiss line. Normally the tubercle (*C*) should measure about one-half inch below the Feiss line.

Again in young persons a notation must be made as to the presence of the juvenile fat pad under the lateral arch, should such persist. Sometimes this fat pad does persist even into the thirties. Some individuals are abundantly blessed with very thick adipose tissue under this arch. It is true, as would be surmised, that fatty tissues deposited beneath the arch might make considerable change in the pedographic picture. They might even produce the picture of a severe flatfoot. Brief mention in such cases should be made on the pedograph in such notations as "Fat pad present" or "Thick adipose tissue present."

READING THE PEDOGRAPH

The Normal Foot.—It is found that average normal weight-bearing gives us an impression which in width extends along the second base line about one-half the distance from the outer border of the pedographic impression (*A*) to the intersection with the first base line at *G,* or from point *A* to point *D* (Figs. 1 and 6). Variations about one-fourth inch either way are normal.

Fallen Longitudinal Arch.—Various degrees of falling of the longitudinal arch produce pedographic impressions entirely over to the first base line (Fig. 7). Such would be extreme, or third degree. Therefore we have dogmatically divided that part of the second base line between *D* and *G* into three equal parts (*D-E; E-F; F-G*), and empirically we find that feet producing impressions widening out to the neighborhood of *E* fall into a class of first degree flatfoot (Fig. 8). In the same way we discover that feet producing impressions widening to point *F* fall into a class of second degree flatfoot. Then any impression extending beyond the point *F* classes the feet as having third degree flatfoot. It must always be remembered, however, that this picture of the widening of the plantar impression must be read with due attention to the findings that are recorded on the margins—the height of the scaphoid and fat findings. Further, attention must always be first directed toward pictorial signs of valgus at the ankle as recorded by the contour line of the foot, an important point to be taken up below (Figs. 2 and 13).

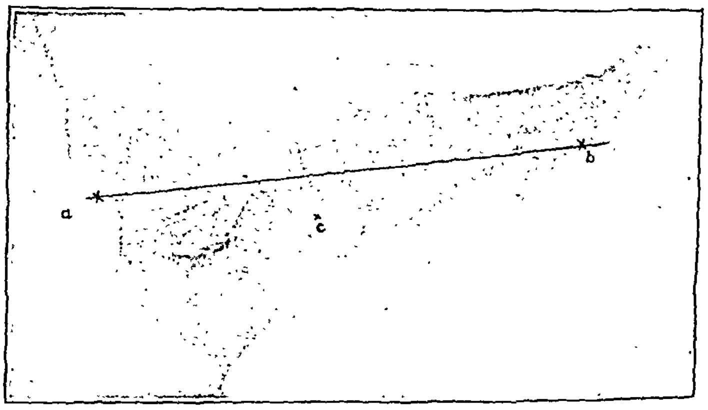

Fig. 5.—Same line as in Figure 4 drawn on roentgenogram.

Cavus, or Raised Longitudinal Arch.—In much the same way cavus is determined. When daylight can be seen beneath the weight-bearing foot we speak of third degree cavus (Fig 9). So the space on the pedograph from *A* to *D* is divided also into three equal parts (*A-B; B-C; C-D*). Should a narrowed impression of a foot reach only to the point *C,* we would have a first degree cavus (Fig. 10). Should it reach only the neighborhood of point *B,* we would have second degree cavus (Fig. 11). And, as stated, with less impression still and light showing through, we have third degree cavus (Fig. 9).

Ankle Valgus and Some Considerations of the Contour Line.—Before considering that most common defect of ankle valgus, it will be necessary to premise with a statement or two regarding the contour line. This line records on the pedograph the integrity of the upper foot, the position of the main ankle and other tarsal joints on weight-bearing. The pencil making the contour line is always held perpendicularly. Contour lines are absolutely without value unless this standard position is maintained. To assist the worker, the Travis block is of great value. Figure 12 shows the level of the upper foot that the perpendicular pencil records as it encircles the foot, making the contour line.

Inspection of the pedograph of the normal foot reveals the fact that the inner contour line as it courses between the points *L* and *M* always passes entirely within, or to the impression side of the first base line, except where it bulges out around the inner malleolus (Figs. 1 and 6).

This inner contour line now assumes considerable importance.

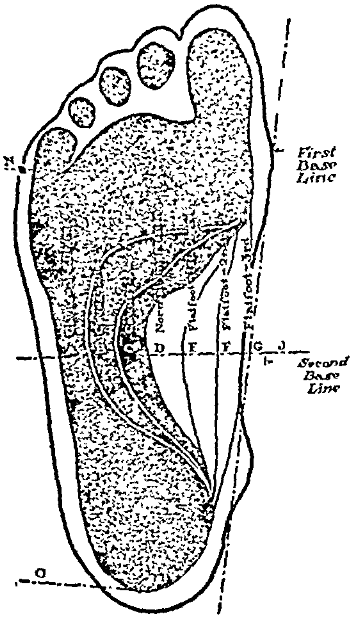

Fig. 6.—Scheme of pedograph interpretation: On second base line the point *D* (half the distance from *A* to *G*) marks the width of the normal impression. The space *AD* is subdivided into three sections to represent the impressions of the three degrees of cavus. The space *DG* is likewise subdivided to represent impressions of the three degrees of flatfoot.

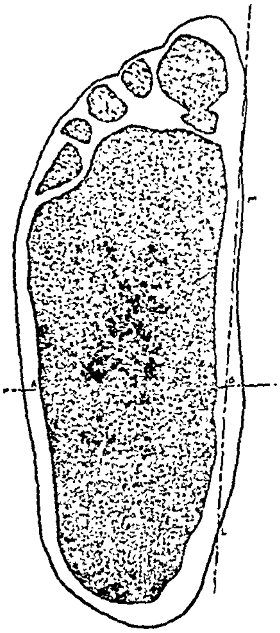

Fig. 7.—Pedograph of third degree flatfoot (with pronation). Extreme falling of the longitudinal arch. Illustrates the common compound condition of flatfoot and ankle valgus, or foot pronation. Feiss line, 1⅝ inches. No fat pad.

As the foot pronates, or assumes a position of ankle valgus—a matter which, contrary to much didactic teaching, takes place largely in the astragalotibial joint—the inner contour line registering the statics of the upper foot falls farther and farther outward toward and often well outside the first base line. The extreme types of true ankle valgus give us a contour line a good half inch to the outside, at the plane of the second base line (*J*, Fig. 13). Such a type of valgus is of third degree. In first and second degree valgus, contour lines of less deviation are recorded (*H* and *I*, Fig. 13).

The term "ankle valgus" is used advisedly. "Genu valgus" and "hallux valgus" have their place in nomenclature, so it is logical and right to encourage "ankle valgus" for a homologous process at the ankle. As intimated above, some writers have advanced theories regarding the etiology of so-called pronation. It is asserted that most of the eversion of the foot takes place in certain minor tarsal joints. A previously described roentgenographic study of a hundred cases of ankle valgus in weight-bearing postures convinces me that fully 80 per cent. of the foot valgus is due to abnormal play in the main ankle joint. The causes for so large a percentage of ankle valgus among the statics of soldiers' feet is easily explained. First, one of the commonest defects in childhood is simple valgus—turning in of the ankle. As most of these cases are untreated, they persist. Again, the sprains of the ankle are most frequently injuries of the internal lateral

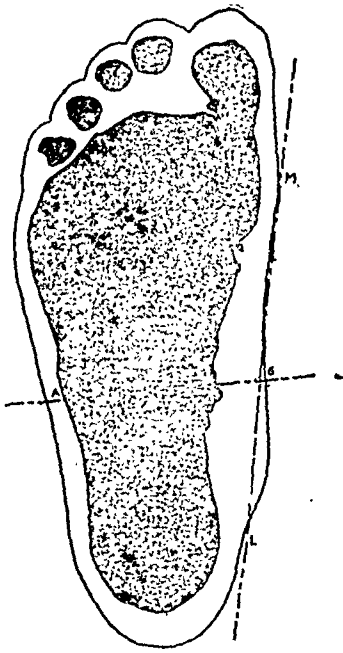

Fig. 8.—Pedograph of first degree flatfoot. Supplemental data: Feiss line, 1⅛ inches. Thick subcutaneous fat.

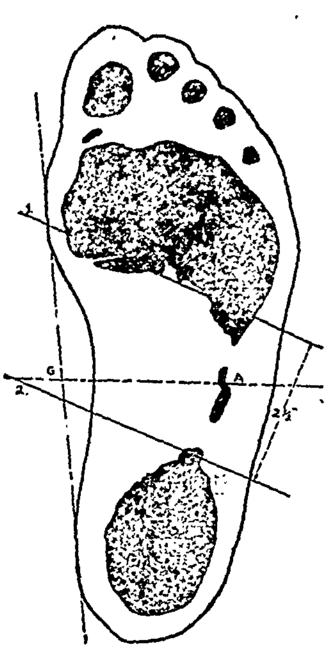

Fig. 9.—Pedograph of third degree cavus. Space of 2½ inches of nonweight-bearing between Planes 1 and 2. Feiss line, minus one-fourth inch.

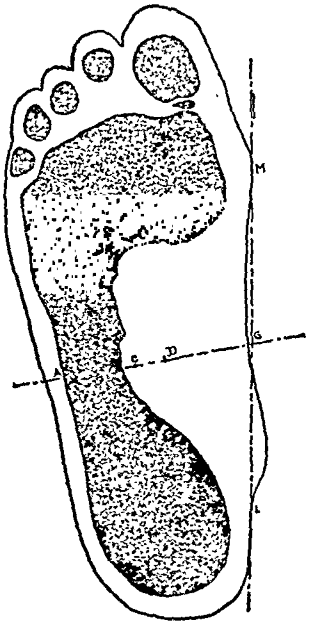

Fig. 10.—Pedograph of first degree cavus. Feiss line, 0. No fat pad.

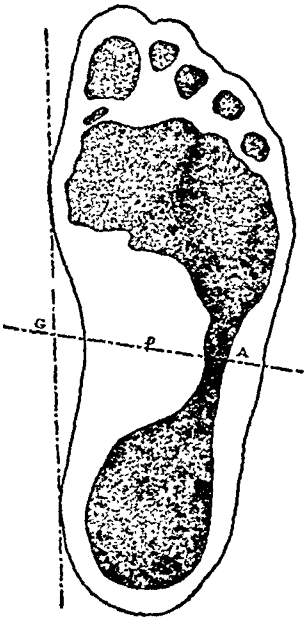

Fig. 11.—Pedograph of second degree cavus. Feiss line, 0.

ligament. Ligamentous repair in so active a joint is often, and probably usually, incomplete, leaving as a sequela a tendency to valgus. Orthopedic surgeons who work intelligently on masses of soldiers in training camps express surprise at the percentage of simple ankle valgus—with no longitudinal arch descent—to the cases of flatfoot. The ratio is as 5 : 1½.

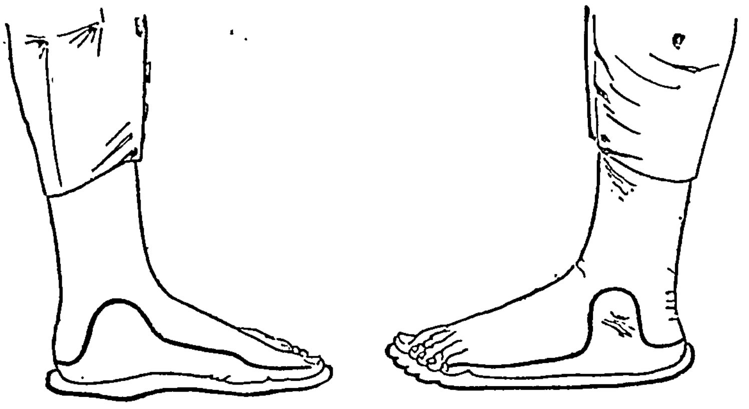

Fig. 12.—Planes of the upper foot recorded by the perpendicularly drawn contour line, shown by black markings on foot.

The pedograph furnishes truthful and accurate data on which to render scientific diagnosis. It is the best guide we have to the intelligent treatment of all the static foot defects.

RESTORING WEIGHT-BEARING WHERE IT BELONGS

We are now in a position to consider the matter of treatment by way of shoe alterations or adjustments as viewed by the discovered pathologic condition. Remembering our aim of restoring weight-bearing to those parts of the foot to which it belongs, let us first consider the most simple condition of cavus.

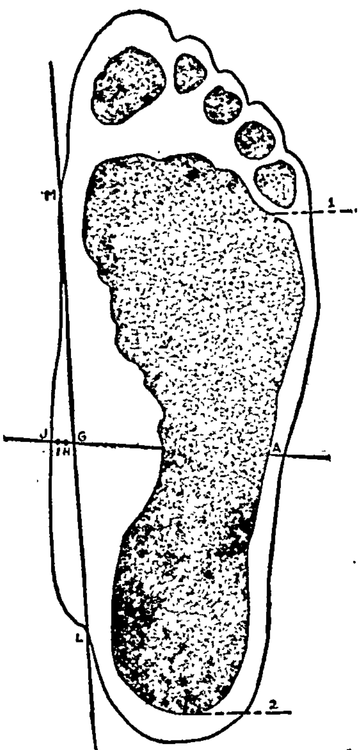

Fig. 13.—Ankle valgus, second degree. Feiss line, 1 inch. No fat present. Note that the inner contour line of the upper foot passes outside the first base line between *L* and *M*.

Cavus.—A third degree cavus gives us such a pedograph as Figure 9. In the center of the foot between Planes 1 and 2 of the figure there can be considered a normal weight-bearing area of several square inches in extent that is not, in the hollow foot wearing a common shoe, bearing any burden whatsoever. Such a cavus is often troublesome because of the shortened ligamentous plantar structures, and because the reduced weight-bearing areas of the dorsum must compensate and bear increased burdens of weight. This type of foot is exceedingly common among our Southern troops, especially from the delta states. Such a foot always is potentially a weak foot. Common shoes never fit it. Fortunately, however, they can easily be so altered that they will be made to fit—the shank and sole can be built up with leather until weight is again distributed evenly on the intended weight-bearing areas. This alteration, the insertion of the rocker shank (Fig. 14), is made by splitting the two layers of the shank and adjacent sole of the shoe, through and through, and the nailing in of a wide double wedge of leather of one or two thicknesses as needed, and of extent wide enough to span the arch of the cavus. The exact width is determined by measurements on the pedograph. As indicated in Figure 9, the approximate width of that particular rocker shank would be 2½ inches. If prepared rocker shanks are on hand, the alterations for a pair of shoes can be made in about eight minutes.

Alterations for Ankle Valgus.—With the same reasoning we approach the treatment of ankle valgus. The pedograph shows that in valgus the patient, instead of bearing weight on the usual planes *A-B-C* (Fig. 15), has shifted inward to some such new plane, as *D-E-F*. Contrary to teaching, the pedograph proves that ankle valgus or foot pronation is much more often a complication of hollow foot than it is of fallen arches. Often the arch is perfectly normal. The entire logic of treatment consists in constructing a solid—though abnormal—foundation in the shoe under the deficient ankle so that weight-bearing is compulsory in the direction of the old plane *A-B-C*, or *where it belongs*. A wedged piece of leather in the shoe does the trick. The best means is the insertion of the tomahawk wedge. These wedges are long, narrow slips of sole leather of the shape shown in Figure 16, the common 8-inch wedge being adaptable for any of the ordinary shoe sizes. They are furnished the shoe shops in three different thicknesses. The receiving shoe is prepared by splitting the layers of the inner side of the sole and shank and separating the inner half of the heel with a cold-chisel. Then the tomahawk wedge is inserted into the sole, shank and heel of the shoe, and nailed in place in such a manner that it raises the entire inner border of the shoe—and greatly stiffens the shank—a point of tremendous importance (Fig. 17). In old cases of valgus, attempts at treatment must be graded. In all cases the beginner errs by forcing correction too fast.

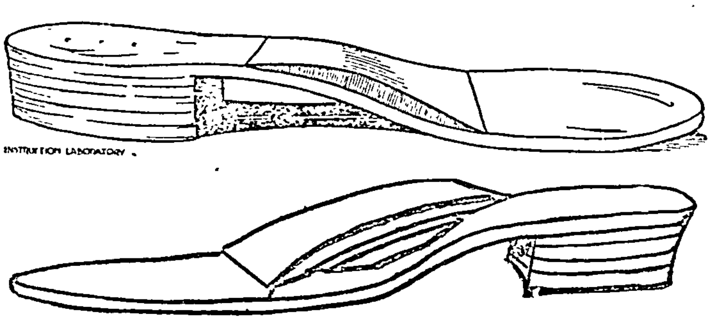

Fig. 14.—Position of rocker shank on the outer sole. The alteration for minor degrees of cavus. With more extreme types the rocker shank of two or more thicknesses of leather is demanded to redistribute weight-bearing. Lower illustration is diagrammatic of positions of leather inserts when multiple.

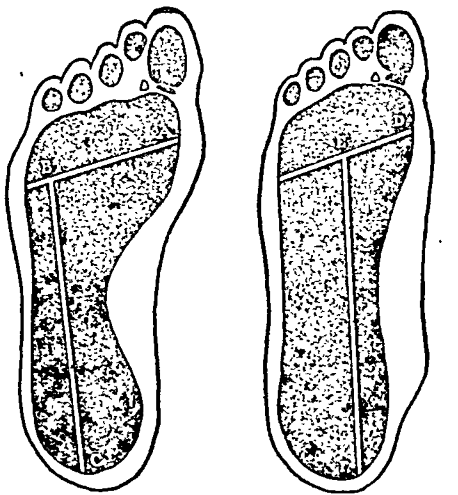

Fig. 15.—General planes of weight-bearing; *A-B-C*, normal planes; *D-E-F*, planes in ankle valgus.

Alterations for Flatfoot.—Most all cases of flattening of the longitudinal arch are accompanied with pronation of the foot and abduction of the forefoot. It is probable that the pronation was the important factor in the descent of the arch. Hence the fundamental principle in treatment is first of all the same problem as in ankle valgus. The tomahawk wedge is inserted in the same way and for the same purpose. Sometimes extra wedges of leather are inserted in the sole with the wedge to correct further the abduction.

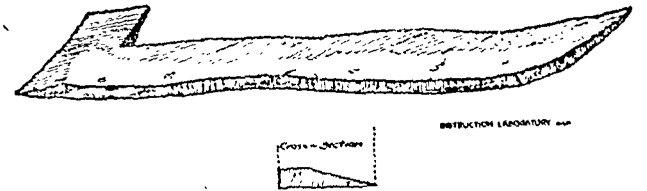

Fig. 16.—Tomahawk wedge, the standard shoe alteration for ankle valgus, to shift weight-bearing to the outer side of the foot; supplied in three thicknesses.

In flatfoot the desired results cannot often be forthcoming from shoe alterations alone. The adjuvant treatment that is reasonable and most profitable consists in various forms of forcible correction and some temporary means of support. Frequently at first the arch has to be forced up into some approach to its original position, and the best means is the Schapps lever or a simple piece of pine 2 by 2 inches and 20 inches long with the edges smoothed. The lever applied by a belt about its end and by means of a figure of 8 about the ankle and outer side of the foot exerts enough force against the padded fallen arch to bring about considerable correction (Fig. 18). No adhesive or plaster-of-Paris dressings are advisable. It is best to support the arch temporarily by some felt pad or padded insole (Fig. 19). The best and quickest results come from the patient repetition of forcible correction and the long persistence in the wedged shoe.

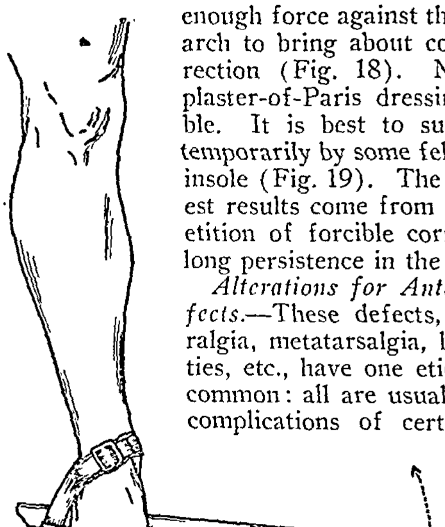

Fig. 18.—Application of Schapps lever for forcible correction of fallen longitudinal arch; protective towel and felt not shown.

Alterations for Anterior Arch Defects.—These defects, Morton's neuralgia, metatarsalgia, bunions, callosities, etc., have one etiologic factor in common: all are usually more or less complications of certain degrees of cavus or high arch.

Evidently Nature intended weight-bearing on the distal halves of the shafts, as well as the ends, of the five metatarsals, and did not intend to cast all the weight on the ends only of these metatarsals, Chinese foot fashion (Fig. 20 *A*). Naturally the higher the longitudinal arch of the foot the less weight there is borne on the metatarsal shafts, and the more on the phalangeal-metatarsal joints. Cavus in the foot breaks down the anterior arch, and secondarily produces the neuralgias and deformities.

The same general principle of restored weight-bearing pertains. First the proper shoe fitting is imperative. Then a shoe alteration known as the anterior heel (Fig. 20 *B*) is employed to restore the burden to these shafts. This anterior heel is a simple piece of leather about 1⅞ to 2⅜ inches wide and as long as the width of the sole of the shoe. This piece is inserted between the sole and shank of the shoe, and between the two layers of leather, obliquely, in such a fashion that it is anchored by nailing or sewing just posterior to the heads of the metatarsals (Fig. 21).

On account of the frequency of these defects, this anterior heel is probably the most useful single shoe alteration in use. It is the counterpart of the Jones cleat, but is much more serviceable and of better appearance. Parenthetically, the anterior heel is a narrow rocker shank applied to a cavus for restoring statics for terminal conditions. Some workers construct the anterior heel higher for the center of the sole than for the two sides. The application of this particular alteration is certainly most satisfactory.

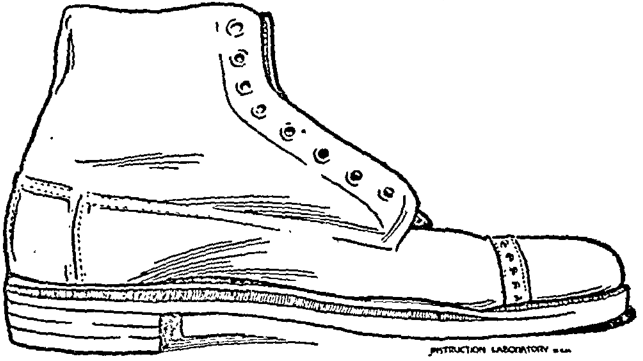

Fig. 17.—The tomahawk wedge in place.

Combined Static Defects.—While each of the foregoing simple static defects has been taken up separately, it must be borne in mind that very frequently two or more defects are found present in the same foot. Ankle valgus and cavus are commonly found together; flatfoot is usually accompanied by valgus; metatarsalgia often complicates all the other defects, etc.

The treatment of such combinations of defects consists in the blending of the alterations for the individual conditions discovered.

Alterations for Short Heel Cords.—The final static foot defect of common Army occurrence is the short heel tendon. Such conditions are often found among ranchers who have always worn high heeled boots. The Army shoe in these cases must have enough leather lifts added to compensate for the shortened tendon.

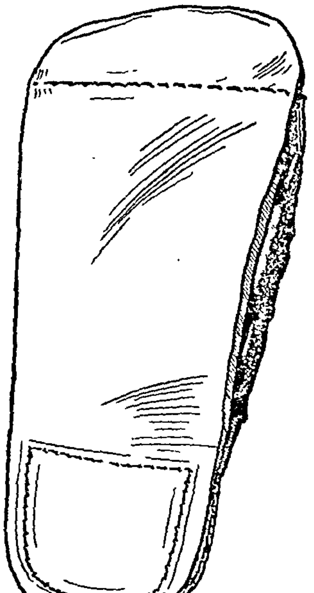

Fig. 19.—Temporary felt supporting insole, for use after forcible correction of flatfoot. Any form of support should be discontinued after two or three weeks.

SUMMARY

Cavus of the first, second or third degree calls for a rocker shank, Size A, B or C.

Ankle valgus of the first, second or third degree calls for a tomahawk wedge, thin, medium or thick.

Flatfoot of the first or second degree calls for tomahawk wedges, thin, medium or thick; forcible correction; and temporary felt support.

Anterior arch defects, metatarsalgia, Morton's neuralgia and anterior callosities call for anterior heels, Size 1, 2 or 3. The width should be specified.

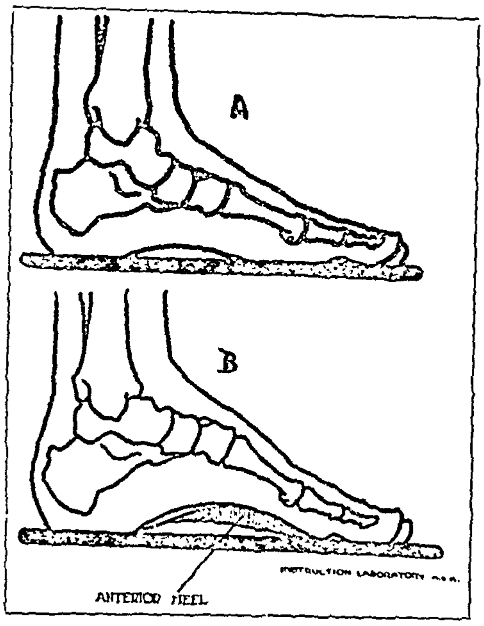

Fig. 20.—*A*, Normal foot; weight-bearing is transmitted to the metatarsals by the soft parts. *B*, hollow foot or cavus that always accompanies anterior arch defects; in this condition the introduction of the anterior heel to restore normal weight-bearing to the metatarsals is necessary.

CONCLUSION

The more experienced the worker in shoe alterations, the less adjuvant treatment usually is necessary to secure results. Mechanical care and skill are mightily important in every alteration, and the alteration is liable to fail with careless, indifferent workers. It must not be surmised that even the experienced do not have to change, raise, lower or alter the positions of their inserts. One of the oldest surgeons often has to revise his prescription as many as three or four times in difficult compound cases before hitting on the right combination. The novice, the careless and those not mechanically inclined do not achieve standard results.

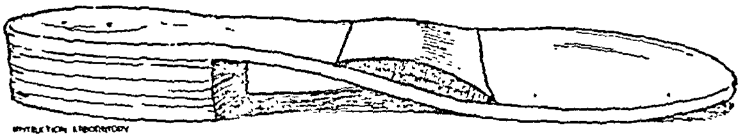

Fig. 21.—Anterior heel in position. This shoe alteration is the most useful single alteration in use in the Army. It successfully meets almost all defects in the forefoot. It can be inserted between the layers of the soles of a pair of Army shoes in seven minutes; this includes individual adjustments.

Effects of Too Much Speed in Military Training.—For a certain period the reports from General Pershing's army showed that the highest mortality from communicable disease was in the National Army and the lowest in the Regular Army. Thus it has been calculated that for a certain period deaths per thousand from pneumonia in the National Army, the National Guard and the Regular Army were in the proportion of 5.65, 4.80, 4.09. I believe that the variation in susceptibility can be ascribed directly to the variation in time of preparation and development which these different units have enjoyed, the development of the National Army having been characterized by intensive training and high speed. I believe that the accumulation of fatigue substances from overtraining for lengthy periods without proper attention to the time element brought about, in the soldiers that I saw, a condition analogous to what we see in the stale athlete, and it is not to be wondered at that the overtrained soldier should be particularly liable to pneumonia, scarlet fever, influenza, etc.—Lieut. D. F. Luby, *Naval Medical Bulletin*, October, 1918.

THE EPIDEMIC OF PNEUMONIA FOLLOWING INFLUENZA AT CAMP LOGAN, TEXAS

PRELIMINARY REPORT

J. N. HALL, M.D. (Denver)
Major, M. C., U. S. Army; Chief of Medical Service
MURRAY C. STONE, M.D. (Springfield, Mo.)
Major, M. C., U. S. Army; Chief of Laboratory Service
AND
JOHN C. SIMPSON, M.D. (Hamburg, Ark.)
Captain, M. C., U. S. Army; Bacteriologist
CAMP LOGAN, HOUSTON, TEXAS

During the period from Sept. 13 to Oct. 8, 1918, inclusive, there were admitted to the base hospital 2,487 cases of influenza, and 416 cases of pneumonia developed, practically all from the influenza cases. The pneumonia has differed in character so widely from the types reported elsewhere that a record seems to be advisable.

Clinically, the disease was lobar pneumonia in all but fifty cases. Generally on the second to the fourth day of the influenza the temperature rose, usually, to about 104, occasionally with a distinct chill. Flatness over one lower lobe, often over both, was found at the first examination. In about half the cases suppressed respiration was noted, but crepitant râles could be elicited in nearly all cases and sharp bronchophony in a considerable number, even from the time of the first examination. Of the whole number of cases, in only four did the disease begin in an upper lobe, although in many of the fatal ones it spread to that region. The flatness was the most pronounced that we have ever seen in acute pneumonia, suggesting fluid rather than consolidated lung, and it generally followed the lines of the lobes involved. The aspirating needle was used rather freely, but fluid was found in only one case.

Because of the frequency of empyema in the hospital during the past winter, and because Major Stone found a little fluid in the pleural cavities in the earlier cases examined postmortem, Capt. J. H. Brown, M. C., Capt. J. E. Cooke, M. C., and Capt. T. P. Caplinger were detailed to examine every case of pneumonia after the fifth day of the disease, and to continue daily examinations in those cases presenting any suggestion of fluid. Yet but few cases were even suspicious. The temperature curve was that of ordinary lobar pneumonia; the pulse rate was rather lower than we have generally observed; crisis was almost unknown. The disease subsided in the patients that recovered with a rather sharp lysis, and recovery has been uneventful.

Approximately 18 per cent. of the cases so far admitted have proved fatal, in general, by the seventh day. Cyanosis has been rather prominent in fatal cases, but not of such degree as in the hemolytic streptococcic bronchopneumonia seen last winter.

Nosebleed was rather frequent. Dry pleurisy, accompanied by much pain, but not with notable effusion, was often noted in the serious cases; delirium was present to such a degree that, for example, nine patients in one fifty-bed ward had to be constantly watched, during the height of the disease. The sputum was commonly red, but less glutinous than the typical pneumonic sputum. Cough was moderate in degree. One case of parotitis and three of phlebitis of the left leg occurred. A most unusual complication has been noted in five cases, namely, the development of surgical emphysema about the root of the neck, spreading downward to the nipple line exactly as in severe whooping cough. We had two examples of this in the severe cough of measles last winter, but no one connected with the hospital had known of it in acute pneumonia. In none of these cases was the cough even moderately severe. Major Stone has suggested that the presence of this complication may be related to the fact that the only case of empyema so far discovered perforated into a bronchus on the seventh day of the disease, at a time when we were purposely delaying operation as advised in recent communications from the office of the Surgeon-General, and in accordance with the lessons of our own experience heretofore. He suggests that the infecting organism apparently damages the lung tissues in such a way as to render perforation by air or pus more frequent than usual.

The few cases of bronchopneumonia presented no especial feature of interest. The epidemic has produced a great number, approximately 10 per cent., of abortive cases of pneumonia. The dulness over a lower lobe in the back with suppressed respiration and crepitant râles, with the usual fever, led us in the early cases to transfer the patients to the pneumonia wards at once. The sudden drop in temperature with recession of all physical signs within twenty-four to forty-eight hours led us to reclassify such cases as abortive pneumonia. Yet in a few cases the physical signs persisted as usual after the subsidence of fever.

During the present epidemic of influenza and pneumonia, 302 sputums have been examined for type determination of pneumococcus and the presence of hemolytic streptococcus with these findings:

Pneumococcus Type I, 1; Type II, 12; Type III, 16; Type IV, 273; hemolytic streptococcus, none.

In nine cases that have come to necropsy, cultures have been made from the involved portion of the lungs, the pleural cavities, the heart blood and the pericardium, and the following organisms found:

Lungs: pneumococcus, 4; influenza bacillus, 1; hemolytic streptococcus, 1; no growth, 3.
Pleural cavities: pneumococcus, 6; sterile, 3.
Heart blood: pneumococcus, 3; sterile, 6.
Pericardium: sterile, 9.

Seventy-nine uncomplicated cases of influenza have been studied by smears and cultures from the throat and sputum, with the following organisms found in either throat or sputum:

Influenza bacillus, 58; pneumococcus, 76; *Micrococcus catarrahlis,* 39; hemolytic streptococcus, 4.

POSTMORTEM FINDINGS

Thirteen cases of pneumonia were examined postmortem between September 20 and October 5. The one on September 20 showed patchy consolidation affecting both lower lobes and was due to the hemolytic streptococcus. Another case showed several old tuberculous cavities in the right lower lobe, which lobe showed well defined consolidation. With these two exceptions all the other cases of the series, eleven in number, presented the typical picture of lobar pneumonia. Complete consolidation of one lobe was present in six cases, there being no instance in which less than this amount of lung was involved. Two lobes were completely involved in four cases, and three lobes in two cases. In every instance in addition to the massive lobar consolidation, partial involvement was present in other lobes. This was found four times in one other lobe, and seven times in two other lobes. This partial involvement was usually a more recent lesion, rather an intense engorgement than a consolidation, and in most instances was found on the side opposite from the older process. There was a decided predilection for the lower lobes, as nine upper lobes showed no gross changes, while this was true of but two lower lobes. The middle lobe was unaffected seven times.

A serofibrinous pleurisy was present eight times, but the fluid was small in amount except in one instance. A small serous exudate was found in two cases. Interlobar pleurisy was not uncommon. Beginning pericarditis was present in three instances. The diagnosis of lobar pneumonia was confirmed histologically.

HISTOLOGIC APPEARANCES FOUND IN THE LUNGS

In the portion of the lung last affected, and usually comprising a part of a lobe on the side opposite the oldest lesion, there appeared scattered areas of round cell infiltration chiefly in the neighborhood of small bronchi, with more or less normal lung tissue between. Many of the alveoli, however, were filled or partly filled with serum and leukocytes, and in some instances with a large amount of blood.

Sections from older lesions, that is, from lobes with complete or nearly complete consolidation, and grossly presenting a firm, dark red, slightly moist surface on section, showed marked engorgement of the capillaries and an exudate of blood, serum, leukocytes, and fibrin filling all the alveoli.

In a few instances the lesions were further advanced, the gross specimen being gray or reddish gray. These sections showed the alveoli uniformly filled with leukocytes and fibrin, and little or no blood. In some there was apparently a softening of the exudate and loosening from the alveolar walls.

MEASURES THAT DIMINISHED SEVERITY OF EPIDEMIC

Statistics show that our base hospital admission rate was the highest in any camp in the United States and that our death rate was the lowest. We are convinced that the low death rate is directly dependent on the care used to have all the sick sent to the hospital, as set forth in the high admission rate. We believe, therefore, that the chief reasons why this severe epidemic was not even more severe are as follows:

At the very beginning, Lieut.-Col. J. M. Willis, M. C., commanding officer of the base hospital, placed sufficient ward space at our disposal so that no overcrowding was necessary; even at the height of the epidemic, when we had nearly 400 cases of pneumonia on hand, a sufficient number of hospital corpsmen were furnished to give every patient brought in prompt attention; surgeons were detached from other departments of the hospital for temporary service on the medical side, and the Surgeon-General promptly sent us 100 additional trained nurses so that there was no lack of trained personnel in any department.

The camp surgeon, Lieut.-Col. J. A. Burket, supplemented the work of our commanding officer by having every suspicious case of influenza traced down at once, and nearly all were sent to hospital immediately. He also gave us great and timely assistance by transferring to us, for the emergency, a number of surgeons from his department.

A RECENT EPIDEMIC OF ACUTE RESPIRATORY INFECTION AT CAMP CUSTER, MICH.*

PRELIMINARY LABORATORY REPORT

WYNDHAM B. BLANTON, M.D. (Richmond, Va.)
Captain, M. C., U. S. Army

AND

ERNEST E. IRONS, M.D. (Chicago)
Lieutenant-Colonel, M. C., U. S. Army
CAMP CUSTER, BATTLE CREEK, MICH.

From a knowledge of what other camps were experiencing with the epidemic of so-called "influenza," and in anticipation of an outbreak of a similar infection in this camp, certain preliminary bacteriologic work was attempted. Several days before any cases of influenza were reported at Camp Custer, a study was begun to determine the prevalent mouth flora of healthy individuals. For this purpose cultures were made from the throats of enlisted men of the Fourteenth Sanitary Train. Smears and cultures on plain blood agar plates were made from the nose and nasopharynx; in all, 357 cultures were taken. The usual mouth organisms were recovered. In addition, 75 per cent. of the cultures showed a hemolyzing streptococcus. In only five cases, or in a little more than 1 per cent., was the influenza bacillus identified. Before these studies could be extended, the epidemic broke. However, this much was apparent: A high percentage of healthy individuals were carrying hemolyzing streptococci somewhere in their respiratory tract. The influenza bacillus was not present in greater numbers than one is accustomed to find this organism in normal throats.

INFLUENZA

Influenza patients who showed no physical signs of pneumonia were first studied. Throat cultures, blood cultures, blood counts and urinalyses were made.

Throat Cultures.—Smears and cultures of the throat were made in 366 cases. Plain blood agar plates were employed, and special care was taken to identify the influenza bacillus. Organisms recovered were: hemolyzing streptococci, 34 per cent.; nonhemolyzing streptococci, 33 per cent.; pneumococci, 12 per cent.; influenza bacilli, 8 per cent.

Blood Cultures.—One hundred and forty cultures were made on these patients at various stages of the disease. In all cases the cultures remained sterile.

Blood Counts.—Five hundred and eighty leukocyte counts were made with the results as shown in Table 1. Seventy per cent. of these counts showed 8,000 cells or less per cubic millimeter. This leukopenia was the most impressive feature of the blood count. The polymorphonuclear leukocytes showed but slight increase over the normal. There has been no conspicuous lymphocytosis, nor other noteworthy features of the blood count.

Urinalyses.—Twenty per cent. of the urines examined have shown albumin. In the majority of cases this was recorded as a faint trace. Casts were an infrequent finding, occurring in 4.7 per cent. of the cases.

PNEUMONIA

It became apparent with the development of a large number of cases of pneumonia that the greatest importance attached to their study. Blood cultures, sputum typings, blood counts and urinalyses were made in as many cases as possible.

Blood Cultures.—Five hundred and ten blood cultures in cases of pneumonia have been made to date. Of these, eleven have shown organisms as follows: hemolyzing streptococcus in ten cases, *Pneumococcus mucosus* once. In other words, only 2 per cent. of pneumonia patients have shown a bacteremia. These cultures were taken from the sickest patients, the majority of whom died shortly after. Many cultures were sterile which were taken only a few hours antemortem. In seven of the eleven cultures that have shown organisms, the blood was taken just prior to death. The evidence clearly points to the fact that the infection of the lungs is only exceptionally accompanied by a bacteremia and that the blood stream is not invaded up to a very late period in the disease. These findings agree with the apparent method of development of the pulmonary lesions and add weight to the belief that a preexisting bronchitis usually unassociated with marked sore throat gives rise to a bronchopneumonia by a process of direct extension. These results are not entirely in keeping with our experience with streptococcus pneumonias of last winter, which usually developed on the basis of a severe primary sore throat and were accompanied by positive blood cultures in 20 per cent. of the cases. It is of interest to note that of the first 430 blood cultures taken, only four showed organisms, less than 1 per cent.; while seven of the last eighty cultures have been positive; this agrees with other later developments in the epidemic.

TABLE 1.—RESULTS OF 1,580 LEUKOCYTE COUNTS MADE BEFORE AND AFTER THE DEVELOPMENT OF PNUEMONIA

Leukocytes per C.Mm.	Prepneumonia Stage		Pneumonia	
	No. of Cases	Per Cent.	No. of Cases	Per Cent.
4,000- 6,000	96	16.5	288	28.8
6,000- 8,000	306	52.7	390	39.0
8,000-12,000	113	19.5	177	17.7
12,000-16,000	48	8.3	83	8.3
16,000-20,000	14	2.5	29	2.9
20,000-30,000	3	0.5	33	3.3
Totals..............	580	....	1,000	
Differential Counts: Occurrence of polymorphonuclear leukocytes: Per Cent.				
40-50	6	2.6	35	3.5
50-60	40	17.4	112	11.2
60-70	60	26.0	260	26.0
70-80	97	42.2	459	45.9
80-90	27	11.8	134	13.4
Totals..............	230	....	1,000	

Sputum.—The character of sputum produced by pneumonia patients was often unsatisfactory for typing because of the extremely critical condition of the patients at the time the collections were attempted. When sputum could be procured it was usually abundant, mucopurulent, and greenish yellow. A fair proportion of sputums were blood streaked, and quite a number were described as rusty. An attempt was made to trace some relation between the type of sputum and the organisms recovered from the sputum during life and the lungs postmortem. None appeared to exist. Rusty sputums were found as often in cases of streptococcus as of pneumococcus infection, and mucopurulent sputums occurred as frequently with one organism as with another. As many sputums were typed as time would permit. From the original specimens smears were made, blood plates streaked, and Avery's rabbit's blood broth inoculated. Agglutinations and precipitations were done after from six to eight hours with the broth suspension. Bile solubility was determined and the results were checked by plain blood agar plates. In all, 740 sputums of pneumonia patients have been typed. The preponderance of streptococci is apparent, especially the nonhemolytic variety. Of the total of 451 streptococci recovered, 30 per cent. were hemolytic and 70 per cent. nonhemolytic. The common mouth pneumococcus was isolated in far higher percentage than usual, Type IV occurring 148 times. The remaining pneumococci were relatively infrequent. The influenza bacillus was identified in thirty-eight instances. In these cases the organism was seen in smears and subsequently recovered from the blood agar plates. In the majority of cases the influenza bacillus was associated with the streptococcus. In only eight instances was it found alone.

---

* Compilation to and including Oct. 22, 1918.

TABLE 2.—TYPES OF ORGANISMS RECOVERED FROM THE SPUTUM OF PNEUMONIA PATIENTS

	Number of Cases	Per Cent. of Total
Pneumococcus:		
Type I	11	1.5
Type II	16	2.15
Type III	16	2.15
Type IV	148	20.00
	—— 191	—— 25.8
Streptococcus:		
Hemolytic	126	17.0
Nonhemolytic	325	43.9
	—— 451	—— 60.9
Influenza	38	5.2
Unsatisfactory	60	8.1
Total	740	

That these results do not accord entirely with the postmortem bacteriology of the lungs and blood is explained by the fact that many patients were moribund before the laboratory was aware of their sickness. From many of the patients sputum could not be had. Therefore, pneumonias caused by the more fatal types of pneumococcus had their bacteriology worked out postmortem, while patients with the less severe infections with the pneumococcus for the most part recovered, and the type was determined during life.

Blood Counts.—A study of 1,000 leukocyte counts in pneumonia patients disclosed a striking lack of reaction on the part of the bone marrow; 67.8 per cent. showed 8,000 or fewer leukocytes per cubic millimeter, and 85.5 per cent. were 12,000 or under per cubic millimeter. These counts agree with those obtained in the prepneumonia period. The secondary invasion of the lungs is apparently without effect in arousing the bone marrow, as is commonly the case in pneumonia. Leukocyte counts have, therefore, been of no value in indicating the onset of pneumonia.

Urinalyses. — Urinalyses on pneumonia patients showed the presence of albumin in 40 per cent., about double the incidence in uncomplicated "influenza" cases. Casts have likewise been a much more frequent occurrence, being present in 22 per cent. of the urines examined.

POSTMORTEM BACTERIOLOGY

The attempt has been made to secure as large a number of lung and heart's blood cultures as possible from fatal cases. A total of 280 fatal cases were thus studied. When necropsies were not performed, lung and heart's blood punctures were made and smears and cultures procured. In all cases examined postmortem, two blocks of consolidated lung were taken in sterile Petri dishes under sterile precautions, and carried to the laboratory for cultures. Plain blood agar plates were streaked and broth cultures inoculated. A number of fresh smears were made from each lung. The heart's blood was cultured in every case. In smears and in cultures particular care was taken to identify all gram-negative bacilli. All bile-soluble gram-positive diplococci that did not come down in pneumococcic serums of Types I, II and III were put through mice for verification. In a number of instances agglutinations were obtained from the mice after failure with rabbit's blood broth suspensions, indicating the importance of the mouse method as a check in Group IV diagnosis.

The result of these cultures is shown in Table 3. No one organism stands out above the others as peculiarly the etiologic factor. Streptococci have been present 142 times in the lungs, and pneumococci seventy-eight times. Hemolytic and nonhemolytic streptococci have appeared about equally as the causative factor. Type II has occurred about twice as frequently as any other type of pneumococcus. Type III has been recovered eighteen times. Small gram-negative bacilli have been recovered five times from the lungs, and three times from the heart's blood. As a usual occurrence only one organism was found in a given case. In three instances in the lungs, the influenza bacillus was found in conjunction with the streptococcus. In two cases it was the sole organism recovered. In the heart's blood it was once present with the streptococcus, once with staphylococcus, and once alone.

The occurrence of such a variety of organisms in pneumonic lungs suggests that they are secondary invaders, the field being prepared by the lowering of resistance incident to a preceding disease, which in this epidemic was in most instances influenza, and that in each instance the invader is probably the organism of which each individual is at the time a carrier. The high percentage of positive heart's blood cultures, taken in conjunction with contradictory antemortem findings, indicates how rapidly and at what a late period in the course of the disease the defense factors in the blood of the patient break down to allow invasion.

TABLE 3.—BACTERIOLOGIC FINDINGS AT NECROPSY FROM THE LUNGS AND HEART'S BLOOD OF PNEUMONIA PATIENTS

	No. Recovered from Lungs	No. Recovered from Heart's Blood
Pneumococcus	78	77
Type I	8	6
Type II	34	33
Type III	18	16
Type IV	18	22
	142	110
	76	62
	66	48
	8	3
	30	29
	22	86

Table 4 shows the sugar reaction of forty-two organisms recovered from the lungs and the heart's blood at necropsy and chosen at random. All of these organisms were bile insoluble, produced no hemolysis on blood mediums, occurred in chains or in pairs, and retained the gentian violet when stained by Gram's method. The variability of inulin fermentation is particularly evident. The absence of mannite fermenters, strains corresponding to *Streptococcus fecalis,* is also noteworthy.

PATHOLOGY

Without exception the deaths from this respiratory epidemic have been due to secondary pneumonia. In no instance has a case come to necropsy in which death occurred from influenzal infection alone. The bodies have been those of well nourished young men, the termination having been reached too quickly for gross external changes. Many of the bodies have shown a moderate degree of corpulence. Reference to Table 5 will show the associated chronic lesions manifested. These have occurred in sufficient number to warrant the belief that in a fair proportion of fatal cases the patients were seriously handicapped beforehand in the battle with their infection.

* In this table — indicates no fermentation, and + indicates fermentation.

For the most part there has been a striking similarity in the appearance of the respiratory organs in the 123 bronchopneumonias coming to necropsy. The mucous membrane of the trachea and bronchi has appeared intensely red, swollen and covered with a mucopurulent exudate. The bronchial glands have been enlarged, soft and reddened on section. The majority of the lungs have been voluminous and heavy. As a general rule the posterior lobes have varied from the remaining lobes, and have presented a surface dark purplish red, sometimes smooth, sometimes roughened and dull from collections of fibrin. They have felt firm throughout, and only occasionally could areas of greater density be made out.

The remaining lobes have shown a greater proportion of air-containing tissue. They have usually presented pale, nonresilient emphysematous patches interspersed with dark red, firm and slightly depressed areas which were to be felt as irregular consolidations extending to various depths into the lung substance. Section of the lung through the lower lobes usually displayed an exceedingly moist cut surface, the slightest pressure forcing to the surface quantities of blood-tinged fluid. This may exist to such a degree as to obscure the underlying process. Again, the confluence of separate patches of consolidation may be so complete as to be confusing, but careful study has usually made evident the bronchial distribution of the process. As a general occurrence, however, patchy areas of consolidation clustered about the bronchi were easily made out. Mucopurulent plugs filled the bronchi and bronchioles. Section of the remaining lobes showed a much drier lesion. Here islands of dark red, often hemorrhagic, consolidated lung showed against a paler background of nonelastic emphysematous pulmonary tissue.

Only one case of lobar pneumonia has occurred. This was caused by a Type I pneumococcus. It appeared during the first days of the epidemic, and its occurrence was undoubtedly fortuitous. Four cases showed the changes of an interstitial bronchopneumonia. Here the white, thickened, pus-filled bronchioles surrounded by hemorrhagic, edematous or indurated areas of consolidation presented a very distinctive picture, entirely different from the great majority of the pneumonic processes seen.

Microscopically, a variety of pulmonary changes have been found, but nothing has been encountered beyond what one is accustomed to expect in bronchopneumonia. The accumulation of inflammatory cells may be patchy, or so massed as to present, in a limited number of sections, an appearance indistinguishable from lobar pneumonia. The exudate may be very dense or it may be thin; in either case edema and congestion have been marked, and so greatly compromised the remaining lung tissue. Polymorphonuclear leukocytes have, as a rule, greatly predominated in the exudate. In other sections, however, the presence of many mononuclear wandering cells and epithelial cells has been noted. Often great quantities of erythrocytes have been massed together in the air cells, sometimes presenting a very striking picture, especially when contiguous to the other air cells stuffed with the inflammatory exudate. Fibrin has not been a prominent part of the exudate except in one case. In a few cases, wide stretches of exudate appear from which all remains of alveolar walls have disappeared. In several such cases, focal areas of disintegration were in process, evidenced by poorly stained, fused masses of cellular débris in which many remains of destroyed nuclei appear. The terminal bronchioles usually contain the same type of exudate described in the alveoli. The mucous membrane is often separated off, and tangled fragments appear free in the exudate. Smears of the lungs usually showed enormous numbers of gram-positive diplococci. It was rare to find organisms arranged in chains. Microscopic study of the remaining organs has not led to any noteworthy disclosures. Eighty of the 123 cases of pneumonia examined *postmortem* showed an associated pleurisy. Thirty-four were described as serofibrinous, twenty-five as serofibrinopurulent, and twenty-one as fibrinous.

Strange as it may seem, there was no difference to be made out in the nature of the process caused by the streptococcus, pneumococcus or influenza bacillus. It was not difficult to distinguish Type III pneumococcus by the sticky exudate and the greater tendency toward confluence, but no matter what the infecting organism, each appeared to produce the same type of pulmonary lesion with equal facility.

Reference to Table 5 will show that there have been no particularly constant extrapulmonary complications. Nine cases have shown hemolytic jaundice, the majority of these appearing late in the epidemic. Four cases showed a massive interstitial emphysema, probably beginning in the multiple rupture of the emphysematous alveoli at the pulmonary hila. There were four cases of pneumococcus meningitis developing in the course of the disease, only two of which came to necropsy, however. There have been relatively few splenic tumors. A firm, congested organ not a great deal larger than normal has been the rule. Acute changes in other parenchymatous organs have been inconspicuous. Marked acute nephritis occurred only three times. Rupture of the rectus muscles was found in four instances. The bone marrow of the femur in all cases studied has appeared to gross examination pale and unreactive.

There has been a noticeable and instructive change in the course and manifestations of the disease in the last days of the epidemic. The leukopenia has disappeared in large measure, twenty of the last thirty-five leukocyte counts having averaged 20,000 cells per cubic millimeter. A far higher percentage of blood cultures show positive results. Of the total of eleven positive findings, seven have been obtained in the last eighty cultures. Synchronous with these changes, necropsy findings have shown older processes in the chest, more fibrin and pus in the pleural cavities, collapsed lungs showing various stages of resolution and extension of the bronchopneumonia.

The average leukocyte count in the streptococcus pneumonias of last winter in this hospital was 17,000, and positive blood cultures were obtained in 20 per cent. of the cases. The duration of the present pneumonias to the time of death has been noticeably shorter than those studied last winter. There is possible significance in the fact that the few pneumonias of the present epidemic that presented a picture at necropsy most like those of last winter are those which have a period of longest illness, in this respect also corresponding to last winter's pneumonias.

In view of the high incidence of pneumonia in the Southern camps, the presence of large numbers of carriers of intestinal parasites has been suggested as possibly a predisposing factor. In search of such factors in the development of pneumonia in the recent Custer epidemic, the incidence of intestinal parasites was investigated. Out of 150 stools of pneumonia patients taken at random and examined, no ova or worms were found. Previous to the outbreak of influenza, a survey of several thousand Southern troops stationed at this camp showed intestinal parasites in 3 per cent. of the cases studied.

To determine the pathogenicity for laboratory animals of various strains of hemolytic and nonhemolytic streptococci recovered at necropsy, mice, rabbits and rats have been inoculated. Of thirty-three inoculated mice, twenty-two died within twenty-four hours, the original organism being recovered postmortem in each instance. Hemolytic and nonhemolytic streptococci were equally fatal. Fourteen rabbits and twelve rats were injected intravenously and subcutaneously with hemolytic streptococci. With the exception of one rabbit and one rat, both of which died of a rapid septicemia, complicated in the case of the rabbit by bronchopneumonia, all of these animals are still living.

SUMMARY

The patient is attacked by a severe acute infection of unknown etiology. In the prepneumonia stage the principal objective signs are those of a marked mucopurulent bronchitis, with high temperature, generalized pains, prostration and a leukopenia. If the process advances, the peribronchial lung tissue is quickly involved by direct extension. A massive bronchopneumonia, in many cases accompanied by acute pulmonary congestion and edema, rapidly develops, which as quickly resolves or goes on to an early termination. The marked leukopenias are probably only one phase of a general overpowering of the defensive forces of the organism. The rarity of concurrent septicemias is doubtless explained by the rapid course of the disease and the mode of origin from the bronchi. The influenza bacillus has played a minor rôle in the production of bronchopneumonia. The infective cause of the antecedent respiratory infection remains undetermined.

Aloes as a Local Sedative.—Friar's balsam, which contains aloes, is used as a sedative for bites, wounds and skin irritations, and is a good preparation for the purpose. F. W. Cock, M.D. (*Lancet*, London, Sept. 7, 1918), says a more pleasant form in which to use aloes for external sedative purposes is a saturated solution of aloes in tincture of tolu. It should be kept in a well stoppered bottle and shaken before using. For bites it should be applied once or twice before any scratching is done. It gives complete relief from the intense itching of harvest bug bites. Cock also recommends tincture of tolu for use in the croup kettle in bronchitis instead of compound tincture of benzoin, as being just as effective and more pleasant than the friar's balsam, in which latter the disagreeable odor of the aloes persists after the aromatic portion has volatilized.

TRANSFUSION IN THE DESPERATE PNEUMONIAS COMPLICATING INFLUENZA

PRELIMINARY REPORT ON THE SUCCESSFUL USE OF TOTAL IMMUNE CITRATED BLOOD

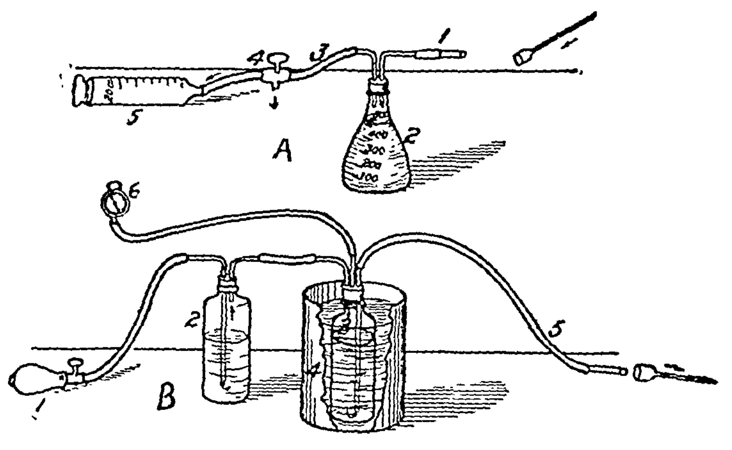
C. W. ROSS, M.D.
Lieutenant, M. C., U. S. Navy

AND

ERWIN J. HUND, M.D. (San Francisco)
Lieutenant, Junior Grade, M. C., U. S. N. R. F.

WASHINGTON, D. C.

The problems presented to the medical personnel supervising the care and treatment of the selected seriously ill civilian employees of the Mare Island Navy Yard were many. These cases represent a small percentage of the total illness of the community, since many of those not seriously attacked went to their homes and did not report to the emergency hospital; and our allotment was principally composed of neglected patients who did not do well with home treatment together with a small proportion of men who had no home or who were taken so suddenly and severely ill that they were unable to get home. The general status of the large majority of patients, with a resultant failure of accepted care and treatment, was most discouraging. The average patient was of the lower type as regards mentality, morality and personal hygiene, and in the main was physically deficient. A large proportion of the patients had been ill and without even simple care for from two to eight days before admission. Fifty per cent. of the pneumonia patients had been ill for four or more days and presented a uniformly low white blood count, from 2,000 to 4,000, extreme toxic cardiopathies with vasomotor palsy, cyanosis, depressed respiratory activity, no localization of the pneumonic process, delirium and tremendous acidosis, with greatly deficient or absent urinary chlorids—conditions that remained uncorrected by the usual care and the desperate efforts of alkalinization by intravenous, subcutaneous and colonic routes, and the stimulation of leukocytosis by the intravenous injection of magnesium sulphate and other supportive measures.



Apparatus for transfusion: *A*, receiving apparatus: 1, receiving tube with very short rubber connection (all paraffined); 2, 500 c.c. Ehrlenmeyer flask (paraffined); 3, suction tube for partially exhausting air from flask; 4, two-way stopcock; 5, 20 c.c. syringe; *B*, apparatus for giving blood to recipient: 1, bulb and valve (from sphygmomanometer); 2, wash bottle (containing mercuric chlorid, 1:500); 3, delivery bottle for citrated blood; 4, vessel containing water at temperature of 43 C.; 5, delivery tube; 6, pressure gage (to measure rate of flow and pressure).

Previous work and excellent results by others with the use of serum from convalescent influenzal pneumonia patients suggested its use to us. However, the difficulty of keeping serum properly, and the uncertainty of testing the old serum as regards compatibility, made it inconvenient to our circumstance. The value of immune serum having been established, no objection to the use of total blood could be seen. The added advantages theoretically to be gained by the use of total blood are:

1. The increased coagulating power caused by the introduction of blood platelets. It was found that in advanced cases the coagulability of the blood was markedly decreased, and was undoubtedly an important factor in allowing this type of pneumonia to progress to a fatal termination.

2. The fact that additional immune bodies are contained in the leukocytes, as first advanced by Metchnikoff and later shown by practical application. Cases progressing to a fatal termination have shown an increasing leukopenia down to 2,000 and lower. We therefore decided to try transfusion of total blood of persons convalescent from two days to six weeks (height of immune content of blood) from pneumonia complicating influenza.

The simplicity, the safety and the brilliant results have been most encouraging.[1] In thirteen cases of the desperate type described, the following brief observations have been noted: Four patients, two of whom had been ill for more than ten days and were at the time moribund, died. Of the remaining nine, all showed definite localization of the pneumonic process with progressively increasing leukocytosis and resolution, rapid clearing of cerebrospinal, respiratory, cardiovascular and renal disturbances, diminished acidosis, and normal temperatures for from twenty-four to seventy-six hours.

We are using from 200 to 400 c.c. of blood at a dose and repeating in from twelve to twenty-four hours if marked results are not obtained. With improved technic we are using it early in the course.

TECHNIC

The usual delirium of the patient, the absence of a surgically clean place for work, and the occasional delay suggested the citrate method as the more practical. The work in emergency wards and tents demanded special care as regards avoidance of infection. This technic has made the procedure safe and simple:

The donors are persons who have had a definite influenza accompanied by a definite pneumonia; the time of selection is from three days to six weeks of convalescence (height of immune body content). Donors are selected from our own patients and from those in surrounding districts. Donors must be subjected to the Wassermann test and clinical examination for syphilis. The donor's and the recipient's blood is tested for isohemolysins and iso-agglutinins.[2] We have found several incompatibilities. All preliminary tests having been made, the blood is taken with a paraffined receiving apparatus from the veins about the anticubital fossa with the usual surgical technic. The apparatus shown in the accompanying illustration allows no exposure of blood to infected air. The paraffined receiving flask minimizes the danger of coagulation. A 1 or 2 per cent. solution of sodium citrate in physiologic sodium chlorid solution is used.

---

[1] Detailed case reports and statistics are to follow in a future report.

[2] Compare Kolmer, J. A.: Practical Text-Book of Infection, Immunity and Specific Therapy, with Special Reference to Immunologic Technic, Ed. 2, Philadelphia, W. B. Saunders Company, 1918.

The blood is transferred to the closed apparatus for delivering the blood to the recipient. A vein is chosen on the arm and the usual technic followed. The pressure gage is of extreme value to control rate and pressure of flow. The citrated blood is kept at proper temperature by a water bath, as shown in the illustration. Exclusive of laboratory tests, it takes approximately forty-five minutes to perform a complete transfusion, taking and giving.

ERYTHEMA MULTIFORME

A CLINICAL AND LABORATORY STUDY OF FORTY-SEVEN CASES

WILLIAM H. GUY, M.D. (Pittsburgh)
Captain, M. C., U. S. Army
CAMP TRAVIS, TEXAS

A definite cause may be ascribed to certain cases of the clinical entity that we call erythema multiforme. The rôle of certain drugs, antitoxins and serums has long been recognized. Cases developing following the ingestion of stale meat, fish, oysters, etc., have been seen sufficiently often to warrant the assumption of direct causation, theoretically being due to the absorption of products of decomposition, bacteria or their products. It would seem that a few reported cases have been due to uterine irritation, a neurosis, etc. Parker and Hazen studied a group of cases occurring in the course of such diseases as typhoid and diphtheria, and were inclined to favor a toxic theory. The theory of absorption of intestinal toxins has long been prominent in the literature. Lain, Chipman and others have recently associated erythema multiforme with focal infections about the teeth, tonsils and accessory air sinuses. Mahon, Vidal and others, from a purely theoretical standpoint, believed a number of cases to be of bacterial origin. Corlett reported a case following a gunshot wound in which a streptococcus was found. Epidemics have been reported by Gaul, Herxheimer, Duhring and others.

I wish to report certain phases of an endemic form of erythema multiforme at Camp Travis, Texas, during the months of February and March, 1918. In all, forty-seven cases were seen, the cutaneous pictures of which varied through all grades with mild erythematous lesions to those showing all manner of individual lesions or a preponderance of vesicular and bullous lesions on skin and mucous membranes. In most of the cases with extensive skin involvement the onset of the disease was heralded by a mild chill or chilly sensations, followed by a febrile reaction that continued over a period of from fourteen to twenty-one days. The temperature curve was irregular but showed a tendency to an evening rise and a morning remission, all ending by lysis. Many of the patients observed had a rise of temperature for two or three days only, the highest recorded temperature being about 100. Several had no abnormal temperature. There were purpuric lesions in approximately 10 per cent. of the cases. Only two gave a history of an attack prior to enlistment, while ten of the forty-seven returned to the hospital with a second attack, one with a third. We early began to investigate every patient that was admitted to the hospital. Careful physical examinations failed to reveal anything noteworthy except that nearly all had hypertrophied and mildly inflamed tonsils. Several had open wounds, the result of recent vaccinations.

LABORATORY FINDINGS

All the urines were practically normal. A few showed a transient albuminuria.

The feces were negative.

In the red cells of the blood there was no change; in the white cells, a moderate leukocytosis, rarely over 11,000.

The hemoglobin was normal.

The differential count showed that the leukocytosis was due to an increase in the polymorphonuclears.

Blood cultures, taken at different times during the course of the disease, were all negative, as were cultures from vesicular and bullous lesions.

Throat swabs showed all the organisms usually found.

Cultures from deep tonsillar crypts showed in thirty cases a hemolytic streptococcus as the predominating organism. Superficial swabs were negative for this organism in the same cases. In nine cases a pyogenic streptococcus was found. In two cases in which the throat and tonsils were negative, the hemolytic streptococcus was isolated from recent vaccination wounds.

At the same time that the cases under consideration were being studied, there was in Camp Travis an epidemic of streptococcic respiratory infections, in the greater number of which the *Streptococcus hemolyticus* was recovered.

Repeated attempts to obtain pure cultures of the *Streptococcus hemolyticus* on defibrinated blood agar failed, and no growth was obtained on plain plus reaction agar.

Serum from infected individuals did not agglutinate the organism.

The opsonic index gave us no information.

It was noted that with the clearing of the exanthem we were unable to obtain the streptococcus with the same facility from the tonsil crypts, but that in those cases with second attacks the organism could again be found. Believing that this organism was possibly the cause of this particular group of cases, acting by elaboration of toxins from a focus in the tonsils, all patients in whom the streptococcus was found were referred for tonsillectomy as soon as the exanthem, temperature, etc., had subsided. In none of these cases was there a recurrence.

CONCLUSIONS

The presence of an endemic form of erythema multiforme, presenting, in addition to the cutaneous manifestations, certain phenomena common to all the acute infectious diseases, makes plausible an infectious theory of etiology. The presence of a hemolytic streptococcus deep in moderately inflamed tonsils, coupled with what scant knowledge we have of the pathogenicity of this particular organism, lends color to the theory. Absence of organisms in the blood stream and skin lesions would seem to indicate the action of toxins generated in a focus of infection rather than a localization of organisms in the skin. The results obtained by tonsillectomy in streptococcus carriers is not conclusive on account of the small number of cases, but it is at least suggestive.

Symptomatic Treatment.—This form of therapy—often disdainfully characterized as "merely symptomatic"—represents, in my view, the very acme of the medical art.—B. Fantus, M.D.

A CLOSED SYSTEM OF DRAINAGE FOR PENETRATING WOUNDS OF THE CHEST *

MARION A. BLANKENHORN, M.D.
(Orville, Ohio)
Captain, M. R. C., U. S. Army
FRANCE

No satisfactory system of drainage for infected war wounds of the chest has been employed that does not produce a more or less open pneumothorax. It is well known that open pneumothorax seriously disturbs the mechanics of respiration and circulation, and exposes large areas of pleural membrane to infection. It is well known also that open pneumothorax is very seldom cured spontaneously.

Recent war surgery has demonstrated satisfactorily that the pleura is able to overcome a very extensive contamination and even a severe infection in a comparatively short time. But to do so the pleura must be in practically a normal condition otherwise, that is, free from accumulations of air or fluid.

Patients operated on early and left with open drainage invariably have done badly. Patients not operated on have developed empyema or become septic. The middle ground offers the best chance, and patients operated on at a selected time and closed again have done remarkably well.

It is not always possible to provide operation and closure at the critical hour; therefore many cases are seen, especially at the base, which demand drainage just as certainly as they demand being spared the embarrassment of an open pneumothorax, in particular those cases reacting violently to infection when there is a small hemothorax and no pneumothorax. In such a case the pleural membranes, respiration and circulation are relatively normal; but when an open pneumothorax is produced, all the membranes are exposed to infection alike, and the patient is seriously damaged by impaired respiration and circulation. It is quite certain that pleural membranes when in approximation combat infection better than when separated, probably for the same reason that wounds of the tissues heal best when all contaminated surfaces are obliterated and accumulations of serum or blood avoided.

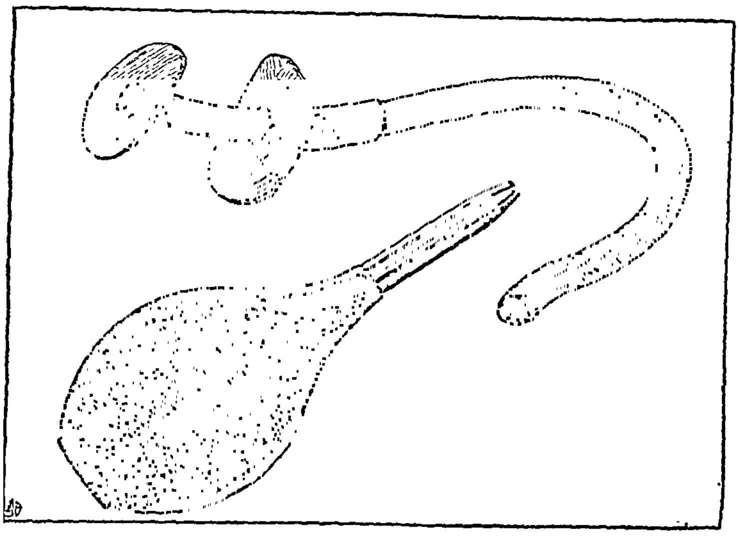


Fig. 1.—Brewer's tube.

Mechanical difficulties have been the chief obstacles in the way of closed drainage. I have seen various devices tried by several confrères in the Royal Army Medical Corps, but when unsuccessful it was usually due to the difficulty in making an anastomosis between a rubber tube and the chest wall. At the Lakeside Unit we have used the Brewer tube with very satisfactory results. This is a rubber tube with flange arrangements (Fig. 1). It is inserted through a rib that has been resected for from one-half to three-fourths inch, and a stab wound through the pleura. It is not necessary to suture the tissues tightly around the tube, for an air tight junction can be made with adhesive tape and dressings together with the flanges of the tube. To maintain a continuous negative pressure on the chest, a stiff rubber bulb is collapsed and connected to the free end of the tube by a glass connection. In civil practice we were using Politzer bags, but at present the rubber bulbs of automobile horns are more available. At operation the surgeon can usually insert the tube through his stab wound with a very little inrush of air, and by manipulating the flanges of the tube prevent a pneumothorax of any appreciable size from forming. What air has entered the chest can be promptly pumped out with the bulb, a large surgical clamp on the tube being used as a valve. By keeping the bulb collapsed and dependent below the wound (Fig. 2), one can make the lung expand normally and at the same time provide a liberal drainage of the pleural sinus.

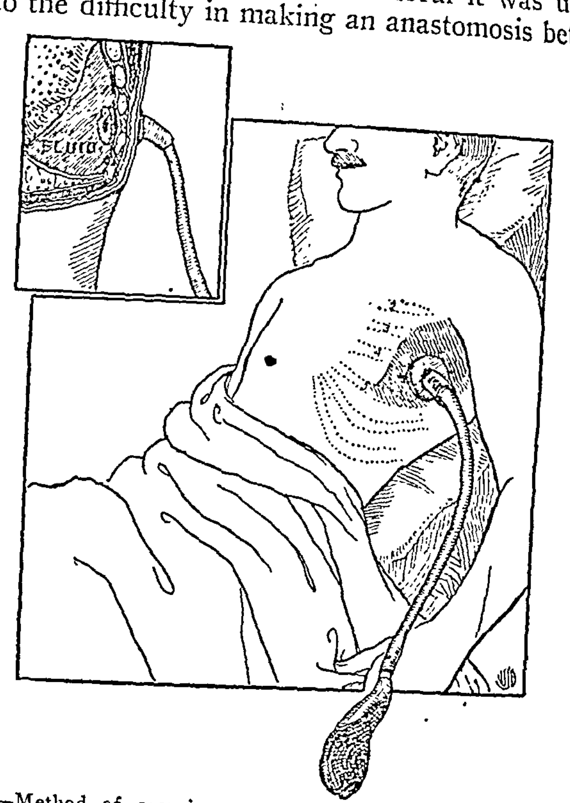

Fig. 2.—Method of securing normal expansion of lung and liberal drainage of pleural sinus.

It has been found that the lung comes down very readily, and breath sounds can be heard almost at once over the space previously occupied by fluid. In all cases a tube will remain tightly in place at least five days, in which time the lung usually has become adherent to the chest wall, and all danger of a large pneumothorax is obviated. After the second or third day, irrigations at a low pressure can be made through the tube by means of the bulb without allowing any

---

* From No. 9 (Lakeside U. S. Army) General Hospital, B. E. F.

inrush of air. It is advisable to use very little pressure in irrigating lest the lung be torn loose from its newly formed adhesions to the chest wall. For the same reason, also, the patient should be protected from coughing during the first five days of the drainage. It is apparent that the treatment of these cases demands the early obliteration of the pleural sinus by adhesions; for when open pneumothorax persists, the lung is frequently collapsed and makes no progress, thus allowing a large expanse of pleura exposed to infection, and a cavity very hard to treat.

When the chest has been explored for a foreign body and drainage is found necessary, it is best to make a drainage through a separate opening, especiallly if the surgical wound is contaminated by the original wound of entry.

On chronic empyemas after gunshot wounds, or otherwise when there has been considerable fibrosis of the visceral pleura, a system of closed drainage with suction will expand the lung much better than blowing exercises; but the methods can be combined. In chronic cases after granulations have surrounded the wound, the tube can be removed, cleansed and replaced; but an air tight junction can be made with the help of adhesive tape.

The stiff rubber bulbs we are now using are found to crack and break if collapsed absolutely flat for a long time. Until better bulbs are available, it is best to collapse them partly, but empty and replace frequently.

Captain Paryzek, who has charge of wounds of the chest at the Lakeside Unit, has treated a number of cases by this method very successfully. His report in detail will soon be available.

RELAPSES AFTER APPARENT RECOVERY IN DELAYED TETANUS

W. L. WHITTEMORE, B.A., M.B. (Tor.)
Major, C. A. M. C.
SHORNCLIFFE, KENT, ENGLAND

Especial interest attaches itself to the two cases of delayed tetanus reported herewith, owing to the fact that after apparent recovery had taken place, there occurred at a later date similar though milder attacks of the same disease. These men were wounded, one three and a half months, and the other nine months previous to the onset of tetanus. In the second case, three months after the patient was wounded an operation was performed in the neighborhood of the healed wound which may have resulted in an acceleration of the development of the disease. In both of these cases the local symptoms and signs were in evidence two and three weeks before the onset of the secondary, generalized tetanus. Esau, I think, observed this characteristic in 1910 in cases of shorter incubation periods. From being mildly ill when the signs were localized, both men became dangerously ill when the symptoms became generalized, showing, in sequence, pain, stiffness, clonic contractures in the wound areas, increasing trismus, photophobia, terror of noise and movement, opisthotonos, with later an emprosthotonos, excessive dyspnea, and cyanosis. Eye complications developed—in one a bad keratitis, in the other an iritis and conjunctivitis. The intelligence remained comparatively unaffected until both had reached very critical stages in their illnesses.

REPORT OF CASES

Case 1.—*History.*—Private L. H. B. (No. 69990), Canadian Field Artillery, aged 22, in the service twenty-four months, was wounded by shrapnel, Oct. 1, 1916, in eleven places, and was given antitoxin on the same day in the field ambulance station. He believes that he was not again inoculated against tetanus. In the left leg there were only two wounds, a small one just above the knee anteriorly which healed very quickly, and a larger one on the left buttock which was drained for two weeks. This wound healed in December, 1916, and appeared as a scar the size of a half crown, situated centrally and posteriorly on the left buttock. I draw attention only to these wounds, as they seem to have been the probable sites of the infection.

Jan. 15, 1917, the patient was discharged from a hospital in Birmingham to a Canadian convalescent hospital, where he was kept for twelve hours before being returned to his unit in the Canadian Field Artillery. The next day, Jan. 16, he complained of a slight stiffness of the leg from the hip down. He was soon given a ten days' furlough and when he returned, Feb. 24, he reported sick. Two days later the pain and stiffness in the leg had become more intense and had begun darting across the back. This continued for the next two weeks, and on March 10 his jaws began to be a little stiff. For the next five days he remained mostly in bed, occasionally feeling flushed and headachy. He did not vomit. He began to find out that he had difficulty in arising from the recumbent position. March 16, he awoke from sleep with his head and shoulders twisted over to the left side. The next day this pleurothotonus continued, and he complained of a general rigidity and found that he could walk only by taking very short steps. He was then, March 17, admitted to No. 11 Canadian General Hospital showing some opisthotonos and delirium. Any movement in bed appeared to throw him into convulsions and to cause great pain. He talked very thickly, opening his jaws with difficulty not more than half an inch. Muscle percussion set up clonic contractures. He perspired freely.

Treatment and Course.—Under a general anesthesia he was given 4,500 units of tetanus antitoxin, intraspinally, 3,000 units, intravenously, and 1,500 units, intramuscularly. His maximum temperature was 102, and his pulse was 134.

The next morning, March 18, rigidity was not quite so marked, and two days later there was so much improvement that it was possible to do lumbar puncture under local anesthesia. One day a serum rash appeared on the body, after inoculation. A complicating keratitis developed in one eye at this time. The opisthotonos gradually gave way to an emprosthotonos. During the thirteen days between March 18 and March 31 he had, altogether, 30,000 units of antitoxin intraspinally, 4,500 units intravenously, and 16,000 units intramuscularly.

April 1, the patient showed great improvement. Trismus had almost disappeared, the recti were less tense, and the temperature curve was running closer to normal.

April 10, he was given subcutaneous inoculation of 500 units of antitoxin—the first in two weeks—and this was followed by only a slight serum reaction.

A note, April 15, stated that the patient was greatly improved, was free from pain and was sitting out of bed. The keratitis seemed no better. His temperature had been normal for fifteen days.

May 29, the patient was transferred to a special hospital for further eye treatment, but the keratitis improved only slowly. His general condition was hardly improved until four months later, when he began to have tremors and some stiffness in the same leg, especially so after resting it.

Relapse.—This showed itself four months later, September 13, and within ten days the condition had become so aggravated that the patient could stand up and begin walking only with great difficulty.

On the eleventh day of the relapse, September 24, he felt some stiffnesss in the jaws. Two days later trismus was marked, and the deep reflexes were markedly exaggerated. He also complained of headache and general stiffness. He

THYROID TOXEMIA AND EXOPHTHALMIC GOITER

Exophthalmic goiter has long been ascribed to a condition of hyperthyroidism despite the difficulties of interpretation which this hypothesis entails. Toxic symptoms, even including exophthalmos, can be induced by ingestion of large quantities of thyroid extract. This well established fact is, perhaps, the most compelling indication for the hyperthyroid theory. Nevertheless it has not sufficed to establish any acceptable or effective uniformity in the mode of treatment; and the dissatisfaction with the attempts to explain all the varied symptoms of exophthalmic goiter as the outcome of hyperactivity of the endocrine glands is manifest in current discussions of the pathogenesis and therapy of this malady.

Reviewing the criticisms of the theory of hyperthyroidism in relation to so-called exophthalmic goiter, Janney[1] has reminded us that the typical exophthalmic goiter contains only from a fiftieth to a twentieth of the total active iodin present in normal thyroids; whereas more, not less, iodin might reasonably be expected to occur in hyperfunctioning glands. Exophthalmic goiter has been reported not infrequently in families having hypothyroid members; sometimes both kinds of symptoms—supposedly hyperthyroid and hypothyroid—are observed in the same person.[2] Contrary to the implications of the hyperthyroid theory, cases of exophthalmic goiter without tumor are not extremely uncommon. Despite the theory, thyroid medication has been reported to benefit some patients suffering from the disease. Finally, similar metabolic disturbances may be present in both alleged hyperthyroid and hypothyroid conditions; the blood picture of exophthalmic goiter is practically identical with that of myxedema and cretinism, so that, as Janney comments, if these conditions are diametrically opposed, such a striking similarity in the metabolic and hematologic findings would scarcely be expected.

Accordingly, Janney[1] has proposed to discard the seemingly inadequate hyperthyroid explanation and substitute for it "dysfunction" of the thyroid to explain the phenomena. In the light of this we can now understand that some of the symptoms of exophthalmic goiter—the thyroid enlargement, cutaneous symptoms, scleroma, osseous changes, and special metabolic manifestations, such as hypoglycemia[3]—are identical with those of a hypothyroidism attributable to a poorly functioning gland. They are truly symptoms of thyroid deficiency which have usually been disregarded in the symptomatology. The more familiar manifestations—psychic stimulation, tremor, tachycardia, increased basal metabolism, etc.—are toxic symptoms which Janney assigns to the liberation of intermediate products of poisonous nature, perhaps owing to the incapacity of the glands to produce the normal thyroid hormone. In exophthalmic goiter, then, a toxic substance is circulating in the system. With a defective endocrine secretory function postulated, it becomes evident how hypothyroid and toxic symptoms may be discovered concomitantly.

With this tentative explanation it becomes clear, furthermore, how clinical improvement may follow suitable—not excessive—thyroid dosage in some cases, particularly when the thyroid deficiency is the etiologically prominent though perhaps not symptomatically conspicuous factor. It is also evident, on the other hand, that the introduction of a normal hormone from without to a dysfunctioning as well as underfunctioning endocrine organ "may not necessarily lead to a cessation of the chemopathologic processes causing the toxic symptoms" of exophthalmic goiter. Probably thyroid treatment of these toxic cases is inadvisable; but when the deficiency symptoms appear, thyroid therapy may actually be indicated,[4] despite the objection which the still current hyperthyroid hypothesis interposes. Is it too much to expect that the stimulus of Janney's recently expressed views[1] will lead to new clinical and therapeutic investigations untrammeled by the handicap of preconceived notions?

THE MINIMAL FAT RATION

During the war the reminder to "save fats" confronted the American citizen many times a day in the form of public announcements through placards, billboards and popular literature, so that it naturally became a part of his war-time creed. One reason for heeding the admonition was furnished by the experience of persons who had been in Europe since the beginning of the war. Many of them were obliged to live on a scanty allowance of fats, and they have reported how disagreeable the deprivation had become. If we may believe the conclusions of extremely careful observers, the lack of fat was perhaps the cause of much of the dietary discomfort in Germany and the element that made the German most dissatisfied with his rations. Indeed, we are told that even when the diet was sufficient, it was not satisfactory if very low in fat.

[2] Bertine, E.: Med. Rec., New York, 1916, **90**, 895.

[3] Thyroid Functions and Therapy, editorial, The Journal A. M. A., Nov. 30, 1918, p. 1826.

[4] Halverson, J. O.; Bergeim, Olaf, and Hawk, P. B.: A Metabolism Study of Goiter, with the Effect of Thyroid and Thymus Treatment, Arch. Int. Med., December, 1916, p. 800.

The apparent reasons for this need not be detailed in this connection. In part we must reckon with the derangement of the dietary habits of people accustomed to liberal supplies of fat. Lack of them alters profoundly the cuisine, the mode of preparation and flavor of familiar items of the diet. Psychologic factors are brought into play as soon as the eating habits of persons are considerably modified. From a more purely physiologic standpoint it must be remembered that the fats are the most concentrated by far among all the foods. They produce a peculiarly satisfying effect, expressed in the layman's statement that they "stay by" one and stave off the feeling of hunger.

By way of contrast and contrary to such extolled virtues of fats, it has recently been suggested that these foods may for the most part be dispensed with, without serious detriment to adult man.[1] In seeking a rational course we may expect to find wisdom in the proposals of the Interallied Scientific Food Commission, of which the American representatives were R. H. Chittenden and Graham Lusk. This group of representative physiologists concluded that the desirable daily minimal ration of fat for an average man should be 75 gm., or 2⅝ ounces. This is considerably below the ascertained intake of men at hard work in cold climates. American lumbermen consume up to 388 gm. (13½ ounces) a day, and Swedish woodcutters from 7 to 13½ ounces, while the ordinary European is content with quantities varying from 1½ to 5½ ounces.

According to the *British Medical Journal,* Starling, who is also a member of the Interallied Commission, has reached the conclusion that although, strictly speaking, there is no evidence for an absolute physiologic minimum of fat in an otherwise abundant diet, the development of the human alimentary canal makes it necessary in practice to supply a considerable proportion of fat in food. In the diet of the infant at the breast, fat gives more than 50 per cent. of the total energy, and the child requires 2 ounces a day of fat up to 10 years. It appears to the *British Medical Journal* that the minimal figure for adults, given by the Scientific Commission, may be diminished without serious detriment to the health of the individual, though probably not without inconvenience and diminution of efficiency, but that it may be considerably increased without interfering with efficiency or with health.

THE PROGRESS OF PREVENTIVE MEDICINE

The most outstanding feature of the war from the medical standpoint has been the really remarkable results obtained in the prevention of disease. War on an unparalleled scale has been going on for more than four years, waged under conditions in themselves calculated to initiate and spread contagious diseases; yet with the exception of typhus fever in Serbia and the recent epidemics of respiratory disease there have been no extensive epidemics such as have occurred in previous wars. Typhoid fever which, up to the time of the Russo-Japanese War, had been the scourge of armies in the field, has been almost a negligible quantity. In the Boer and Spanish-American wars, typhoid killed and incapacitated thousands. In the Russo-Japanese War the real beginning was made and typhoid checked. In the war just over, it has been entirely robbed of its sting. As with typhoid, so with the other war pestilences. Trench fever after a short time was brought under control through scientific investigation. It has been not only by preventive measures in warding off epidemics but also by close attention to personal hygiene that health in the armies on the western front has been maintained at a high standard. Preventive medicine during the past twenty years has progressed apace, and its value has been greatly emphasized by its strong showing in the war. The experience thus gained should now be put to good use in civilian communities.

If masses of men enduring the stress and strain of modern warfare can be kept healthy by the enforcement of sanitary and hygienic measures, it will certainly be reasonable to suppose that the general health of a civilian population cannot fail to be greatly benefited by the adoption of similar methods.

In Great Britain a strong movement is under way for the prompt establishment of a ministry of health. The medical profession and most of the public are convinced, first, that much disease is preventable and, secondly, that it should be prevented. Moreover, members of the medical profession and the people are agreed that this object will be best attained by the formation of a ministry of health. However, the views of the man in the street and of the thoughtful medical man differ somewhat widely as to exactly what the functions of a ministry of health should be. The British public and apparently some medical men are imbued with the idea that such a ministry will provide the machinery whereby the sick may be treated at the cost of the state and that physicians engaged in this work will be a species of government servant. The medical profession, as a whole, on the other hand, regards the matter from quite a different aspect. It is recognized that a national department of health will be concerned chiefly with preventive medicine, and in the opinion of perhaps the majority of medical men its ideal form will probably be that of a bureau in which scientific medicine will hold sway and, in consequence, the care for the health of the people will be conducted on strictly scientific lines.

---

[1] The Daily Press and the "Futilities of Contemporary Science," editorial, THE JOURNAL A. M. A., Sept. 28, 1918, p. 1060.

The scope of preventive medicine has widened immensely; it is the branch of medicine fraught with almost unlimited potentialities and possibilities. Preventive medicine is not now restricted to purely sanitary measures, the supervision of drainage, sewage and water supply, the destruction of disease-bearing insects and so on. As a matter of fact, the science of preventive medicine comprises every method that may prevent disease. Personal and domestic hygiene are factors of the first importance in the improvement of public health. Because preventive medicine covers so much and because it is essential to the happiness and prosperity of a nation, the demand is arising in many civilized countries for the establishment of national departments of health. The only way by which the object can be achieved is by earnest and intelligent cooperation between the general public and the medical profession.

SCURVY AND ANTISCORBUTICS

The evidence that the antineuritic and antiscorbutic properties in foods are not identical, since they behave quite differently toward absorbents, was recently mentioned in these columns.[1] This raises the question as to the comparative etiology of the types of disorder corrected by the use of antineuritic and antiscorbutic foods, respectively. Polyneuritis, as it is exemplified in the disease beriberi, is today admitted to be a dietary deficiency disorder attributable to the lack of a specific vitamin in the regimen. Is scurvy a disease of a different sort, or does it also correspond to the type lately designated as an avitaminosis?

McCollum and Pitz[2] reject the vitamin hypothesis in explanation of the genesis of scurvy. They insist that the disease is the outcome of faulty intestinal conditions; that it is not due to any deficiency in the diet, but rather is the result of chronic constipation caused by the physical texture of a "scurvy-producing" diet. The contention of these investigators is based on observations on guinea-pigs, the classic animals for the production of experimental scurvy. These animals are alleged to need foods that produce a bulky mass of easily eliminated feces. Thus guinea-pigs that die of scurvy generally show an empty stomach and a gorged cecum, we are told; and it is further stated that the scurvy can be both prevented and cured by the administration of laxatives, without any other alteration in the diet.

If the existence of a condition of chronic intestinal stasis is sufficient to account for so serious a malady as scurvy, without taking into account any specific qualities of the food, surely this information is of the first importance for human therapy and prophylaxis. It is hard to believe that the antiscorbutic effect of the conventional small portion of orange juice can reside solely in a laxative effect of this substance. However, contradictory evidence is beginning to appear in the scientific literature. Chick, Hume and Skelton[3] of the Lister Institute of Preventive Medicine in London deny that chronic constipation is a constant concomitant of guinea-pig scurvy. Instances are cited in which modifications in diet, to which no extra laxative effect can be attributed, have cured or prevented the disease. Experiments are also described in which the administration of a laxative alone has failed to cure or prevent scurvy.

To many unbiased students the chief obstacle to the acceptance of a "vitamin hypothesis" for the genesis of scurvy has been the fact that the disease manifests itself even when milk is included in the dietary. Popularly, milk is at present looked on as an exceptionally abundant source of all forms of vitamins. We have already called attention to the researches of Osborne and Mendel[4] showing that milk is not as rich in the water-soluble vitamin as one not familiar with the experimental evidence for this property of the food might assume. Now we are further told by the British investigators that "milk is evidently a food poor in the antiscurvy accessory factor, and a ration large in comparison with that of other antiscorbutic materials is necessary to afford satisfactory protection from scurvy."

As a "working theory," it seems safer at present to postulate that experimental scurvy, such as can be induced in the guinea-pig, is due to the deficiency in the diet of a specific food factor of the vitamin type. The latest investigations lend favor to the hypothesis that it is analogous in etiology and general method of cure with human scurvy. Chick, Hume and Skelton, making application of these facts and the known sensitiveness of the antiscorbutic property of milk to heat, call attention to the risk, in infant feeding with cow's milk, of "tampering with a substance which even in the fresh condition is but feebly antiscorbutic." In order to give the child optimal conditions, it is urged that whenever milk is heated in any way, or dried, an additional source of antiscorbutic vitamin should be provided. Experience points to orange juice as the most suitable source, and the precaution of using it is the wisest measure so long as the scientists disagree.

Nonessential Consumption.—The best definition that I have heard of nonessential consumption is "all consumption not required for maintaining physical efficiency."—H. G. Moulton, *Economist.*

Current Comment

THE GOVERNMENT AND THE HEALTH OF WORKERS

The economic independence of a country depends largely on the efficiency of its production. The efficiency of modern industry has resulted from the development and wise use of such factors as raw materials, machinery, production processes, transportation, trade relations and the like. A still greater efficiency will come when the same careful attention is given to human beings as factors in production. Scientific methods are being applied to reduce wastes to a minimum; and yet there are no wastes comparable in value and costliness with the waste of labor turnover. Though war is the arch destroyer, happily it compels conservation and construction. America's participation in the war has made us realize the value of human resources. Yet even here we have been more concerned about aeroplanes or shells that were found defective than about the hundreds of thousands of young men whom our draft boards found unfit for military service. Our industrial army is recruited from the same population as are our soldiers and sailors. Physical defect lessens the efficiency of a working man quite as it does that of a fighting man. Of course, a physically handicapped man who cannot be safely used in the Army may be efficiently placed in industry, but placement is another of industry's problems awaiting solution. The federal government is sensitive to the urgency of the problems relating to the health and physical fitness of working people and has created in the Department of Labor a Working Conditions Service, one division of which is cooperating with the United States Public Health Service in a study of industrial health problems.[1] The health hazards of modern industry present a much more difficult problem than do the accident hazards. The economic losses due to illness and decreased physical energy far outweigh those caused by accidents. It is not enough to discover the diseases directly traceable to occupation and to develop means for their prevention. There is the far more delicate and difficult task of determining the relation between health and efficiency and of preventing waste by promoting health. Extensive research should be, and we believe is, an essential part of the program that the government contemplates. Careful study should be made of plant sanitation, of the health of employees, of the medical work now being done in industry, of occupational injuries, of the relation of hours of labor to health and production, and of provisions for safety. Out of this effort ought to come established scientific principles on which the working conditions of the future may be based. We must not, however, lose sight of the fact that many of the defects of adults result from remediable conditions of children. It is to be hoped that in a comprehensive study of so important a question as the health of working people, the government will continue to give especially careful consideration to the bearing that the hygiene of childhood might have on the health and efficiency of our adult population.

PRACTICAL ECONOMY

Last year, attention was called editorially to the large increase in the cost of production of The Journal on account of abnormally high prices of paper, supplies, labor, postage, etc. In addition, letter postage increased 50 per cent. To quote: "Under the new postage rate the cost for sending the customary bills for Fellowship and subscriptions and later receipts would total over $4,000. One half of this can be saved if each Fellow and subscriber will remit without being individually notified by mail. It is believed that many will gladly do this. Under the circumstances, such notification will not be sent on the first of the year as heretofore." In lieu of sending bills, a remittance slip was inserted in The Journal. The result was most satisfactory. More than 20,000 sent in their dues and subscriptions without waiting for the bill. This year the same plan will be followed and next week a slip will be inserted in The Journal.

THE NATIONAL BOARD OF MEDICAL EXAMINERS

During the past two weeks the National Board of Medical Examiners[1] held its sixth examination, conducting it simultaneously in New York and Chicago. In Chicago, out of fifty-eight who applied—mostly interns in hospitals—only thirteen appeared to take the examination. The explanation is that these interns could not leave their hospital duties for the time required, and that substitutes for the hospital duties could not be obtained. That so few recent graduates in medicine avail themselves of the privilege of taking this examination is surprising, since in after years the National Board's certificate is sure to mean much to them. This certificate has already received recognition, either by board rulings or by amendments to the medical practice acts, in eleven states;[2] and in several others, efforts to amend the practice acts will soon be made. The holder of this certificate is eligible for the Medical Corps of the United States Army and the United States Navy, subject only to his passing the required physical examination. As a result of the war there is bound to be a closer union between the medical men of the Allied nations, making it probable that in time this certificate will receive recognition in foreign countries. Even now, the National Board is planning to make a trip to France, where the examination of a number of American physicians can be witnessed by representatives of England, France and Italy, with the hope that, based on the certificate of this board, reci-

---

[1] General News, this issue, p. 2008.

[1] A descriptive statement regarding this board is contained in the Report of the Council on Medical Education to the House of Delegates of the American Medical Association. See The Journal, June 15, 1918, p. 1846.

[2] These states are Colorado, Delaware, Idaho, Kentucky, Maryland, New Hampshire, North Carolina, North Dakota, Pennsylvania, Rhode Island and Vermont.

St. Robert Fielg Library

procity in medical practice can be arranged with those countries. The certificate already stands as a badge of merit to its possessor. Up to, but not including, the present examination, the board has examined ninety-three applicants, of whom seventy-two passed and twenty-one (22.6 per cent.) failed. This high percentage of failures shows at once the thorough character of the examination. For, considering the fact that only graduates of Class A medical schools are admitted to the examination, this percentage of failures is high. Applicants must also have completed an internship in a hospital.

THE CITRIC ACID IN MILK

"Milk is vital to national health and efficiency." We can conserve wheat and meat, sugar and fats, and be none the worse for it, but we must use milk, says the Food Guide of the United States Food Administration.[1] The chemist is still far from knowing all about this unique food. Only a few persons adequately realize that, in addition to the familiar nutrients, milk contains in small quantities a considerable number of organic substances. Thus there are phosphatids[2] and those subtle, little understood constituents at present termed vitamins. It is thirty years since citric acid was discovered as a normal constituent of cow's milk.[3] Although the substance is often mentioned in textbooks on the chemistry of milk, the statements usually made are of the vague sort that characterize information transmitted in the traditional way. Of the accuracy of the assertion that citric acid is present in milk there can no longer be any doubt. At the laboratory of agricultural chemistry in the University of Wisconsin, Sommer and Hart[4] have recently isolated and identified the compound anew, and have ascertained the content to amount to approximately 0.2 per cent. of the milk, or 2 per cent. of the milk solids. Citric acid is a recognized constituent of various "acid" fruit juices and vegetables, the familiar antiscorbutic properties of which have actually been ascribed to it.[5] Sommer and Hart have pointed out that if citric acid actually is an antiscorbutic and if there was a decrease in the content of this acid on heating milk, this fact might be used to explain, as often stated, why heated milk should be more conducive than raw milk to the production of scurvy. However, the experiments show that citric acid is not destroyed in the heating of milk even in an autoclave at 15 pounds pressure for one hour. Furthermore, the citric acid salts of milk are not changed to an insoluble form on heating. Thus the question of the physiologic function of citric acid in the diet remains unanswered.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending December 6, there were in the Medical Corps 31,104 officers, a decrease of ninety-three since the previous week. This personnel includes three major-generals, five brigadier-generals, 205 colonels, 441 lieutenant-colonels, 2,426 majors, 10,103 captains and 17,921 lieutenants. There were in active service 30,379, a decrease of twenty-nine since the previous week. Discharges to date include 3,674 officers.

Promotions for Medical Officers

On December 3 Col. Walter D. McCaw and Major-Gen. Robert E. Noble were nominated for brigadier-general in the Medical Corps of the Regular Army. The rank of major-general held by Brigadier-General Noble was for the period of the emergency only.

Field Hospital Arrives in Russia

Field Hospital and Ambulance Company No. 4, commanded by Major John H. H. Scudder, M. C., U. S. Army, Philadelphia, which left the Philippines, September 6, for duty with the American Expeditionary Forces in Siberia, arrived in Vladivostok, September 14.

Awards for Heroism

The Distinguished Service Cross has been awarded to Lieut. James G. Hall, M. C., U. S. Army, assigned, 360th Infantry, "For extraordinary heroism in action near Montoville, Sept. 12 and 13, 1918. In spite of severe wounds, including two broken ribs, received in his first day of action, Lieutenant Hall stayed at his post for thirty-six hours administering first aid to wounded throughout the combat. Numbers of lives were saved by his devotion to duty."

Surgeon-General Relinquishes Control of Medical Schools and Intern Service

A circular letter dated December 2 from the Surgeon-General to deans of medical schools gives notice that the control over them through the Medical Enlisted Reserve Corps has been relinquished. The control was based on the draft, and medical students were enrolled in the Medical Enlisted Reserve Corps so that they might be retained at their studies so long as their scholarship remained satisfactory. The cessation of the draft makes this control no longer necessary and it has been relinquished. It is stated, however, that since students voluntarily enrolled in the Medical Enlisted Reserve Corps "for the duration of the emergency," they will be subject to the terms of their enrolment until it has been officially declared that the "emergency" has ceased. For all practical purposes, however, the students are on the same basis as civilians. It is only "in time of actual or threatened hostilities" that they would be called to active service, the probability of which is so remote that it may be disregarded. The Medical Department surrenders to the schools all supervision over their students from an educational standpoint.

The Surgeon-General has also relinquished the supervision of intern service in hospitals. Attention is called, however, to the fact that, where internships have been approved by the Surgeon-General, an agreement was entered into between the interns and the hospitals in which they were serving, and that a cessation of supervision by the Surgeon-General will not in any way impair the obligations imposed by these agreements.

Wounded and Sick Soldiers from A. E. F. to Be Placed in Hospitals Near Homes

The Surgeon-General announces that the Hospital Division has perfected plans for the care of sick and wounded soldiers from overseas in hospitals in the sections from which they were inducted and which will not be more than 300 miles from the relatives of the patients. The Hospital Division now has seventy-five of these hospitals with a capacity of 104,231 beds which were turned over to the Surgeon-General by the general staff; these do not include the fifteen hospitals located at the ports of debarkation at New York and Newport News which have a bed capacity of 22,066.

These hospitals are located in sixteen districts as follows:

No. 1.—General Hospital No. 10, Boston, Mass.; General Hospital No. 16, New Haven, Conn.; General Hospital, East Norfolk, Mass.; General Hospital No. 30, Plattsburg Barracks, N. Y.; Base Hospital, Camp Devens, Mass.

No. 2.—General Hospital No. 1, Williamsbridge, N. Y.; General Hospital No. 38, East View, N. Y.; Base Hospital, Camp Upton, N. Y.

No. 3.—General Hospital No. 3, Colonia, N. J.; General Hospital No. 4, Fort Porter; General Hospital No. 5, Fort Ontario, N. Y.; General Hospital No. 8, Otisville, N. Y.; General Hospital No. 9, Lakewood, N. J.; General Hospital No. 11, Cape May, N. J.; General Hospital No. 13, Dansville, N. Y.; General Hospital No. 37, Madison Barracks, N. Y.; Base Hospital, Camp Dix, N. J.

No. 4.—General Hospital No. 2, Fort McHenry, Md.; General Hospital No. 7, Roland Park, Md.; General Hospital No. 31, Carlisle, Pa.; Walter Reed General Hospital, Takoma Park, D. C.; Base Hospital, Camp Meade, Md.

No. 5.—General Hospital No. 17, Markleton, Pa.; General Hospital No. 22, Richmond, Va.; General Hosiptal No. 24, Pittsburgh, Pa.; Base Hosiptal, Camp Lee, Va.

No. 6.—General Hospital No. 12, Biltmore, N. C.; General Hospital No. 18, Waynesville, N. C.; General Hospital No. 19, Azalea, N. C.; General Hospital No. 23, Hot Springs, N. C.; Base Hospital, Camp Greene, N. C.; Base Hospital, Camp Sevier, S. C.; Base Hospital, Camp Wadsworth, S. C.; Base Hospital, Camp Jackson, S. C.

No. 7.—General Hospital No. 6, Fort McPherson, Ga.; General Hospital No. 14, Fort Oglethorpe, Ga.; Base Hospital, Camp Gordon, Ga.; Base Hospital, Camp Hancock, Ga.; Base Hospital, Camp Wheeler, Ga.; Base Hospital, Camp McClellan, Ala.; Base Hospital, Camp Sheridan, Ala.

No. 8.—Base Hospital, Camp Sherman, Ohio.

No. 9.—General Hospital No. 25, Fort Benjamin Harrison, Ind.; General Hospital, No. 35, West Baden, Ind.; Base Hospital, Camp Zachary Taylor, Ky.

No. 10.—General Hospital No. 36, Detroit, Mich.; Base Hospital, Camp Custer, Mich.

No. 11.—Cooper-Monatha Hotel, Chicago, Ill.; General Hospital No. 28, Fort Sheridan, Ill ; Base Hospital, Camp Grant, Ill.

No. 12.—Army and Navy General Hospital, Hot Springs, Ark.; General Hospital No. 33, Fort Logan H. Roots, Ark.; Base Hospital, Camp Pike, Ark.; Base Hospital, Camp Beauregard, La.; Base Hospital, Camp Shelby, Miss.

No. 13.—General Hospital No. 26, Fort Des Moines, Iowa; General Hospital No. 29, Fort Snelling, Minn.; Base Hospital, Camp Dodge, Iowa.

No. 14.—General Hospital, Fort Bayard, N. M.; General Hospital No. 20, Whipple Barracks, Ariz.; General Hospital No. 21, Denver, Colo.; Base Hospital, Camp Cody, N. M.; Base Hospital, Fort Riley, Kan.

No. 15.—General Hospital No. 16, Corpus Christi, Texas; Base Hospital, Camp Logan, Texas; Base Hospital, Camp Travis, Texas; Base Hospital, Fort Sam Houston, Texas; Base Hospital, Camp MacArthur, Texas; Base Hospital, Camp Bowie, Texas; Base Hospital, Fort Sill, Okla.; Base Hospital, Fort Bliss, Texas.

No. 16.—General Hospital No. 27, Fort Douglas, Utah; Letterman General Hospital, San Francisco, Calif.; Base Hospital, Camp Kearney, Calif.; Base Hospital, Camp Fremont, Calif.; Base Hospital, Camp Lewis, Wash.

The 50,000 wounded which it is expected will be sent to these hospitals at the end of four months will be transported from the hospitals at the ports of debarkation in special hospital trains when unable to travel in Pullman sleepers. There are four of these trains composed of seven cars each with a capacity of 172 to each train. Special hospital kitchen cars, of which there are twenty, will be attached to the Pullmans containing patients.

Since it has acquired the base hospitals the Hospital Division has recommended that the following properties which were to have been used as general hospitals, be returned to their owners:

New Field Museum, Chicago, Ill.
Exposition Park, Rochester, N. Y.
State School for the Deaf, Columbus, Ohio.
Richman Brothers Building, Cleveland, Ohio.
Deutsches Turnverein, Cleveland, Ohio.
High School, Cincinnati, Ohio.
City Sanatorium, St. Louis, Mo.
Ford Building, Milwaukee, Wis.
Brockman Store Building, Milwaukee, Wis.
Badger State Sales Co. Building, Milwaukee, Wis.
Woodstock Apartments, Milwaukee, Wis.
State School for the Blind, and Galloway Hospital, Nashville, Tenn.
Sophie Newcomb School and Tulane University buildings, New Orleans, La.
Byberry Farms, Philadelphia, Pa.
New Orleans Elks' Hospital.
Seaview Hospital, New York City.
Ford Building, Des Moines, Iowa.
St. Catherine's Home, Des Moines, Iowa.
North Brothers Island, N. Y.
Catholic Orphan Society, New York City.

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Surg. HUGH S. CUMMING, detailed by the President for duty in Europe *to investigate* sanitary conditions at ports from which troops will be returned.

Surg. L. P. H. BAHRENBURG, proceed to Jefferson City and Columbia, Mo., and other necessary *points to* exhibit films in connection with the control of venereal disease.

Surg. HUGH DE VALIN, proceed to Astoria, Oregon, to determine public health value of contemplated improvements.

Passed Asst. Surg. F. A. CARMELIA, *proceed* to Harrisburg, Pa., *for* conference relative to discontinuance of influenza control work in the state of Pennsylvania.

Proceed to Wheeling, W. Va., for *conference relative* to discontinuance of influenza control work in the state of West Virginia.

Passed Asst. Surg. HOWARD F. SMITH, assume charge under Surgeon Frost of epidemiological studies of influenza in the state of Maryland.

Asst. Surg. W. F. WAGENBACH, proceed to Norfolk, Va., for temporary duty.

Asst. Surg. H. S. MUSTARD, proceed to necessary points outside of Philadelphia, Pa., for inspection *work* in connection with the hygiene and sanitation of the Emergency Fleet Corporation.

Prof. E. B. PHELPS, proceed to Milwaukee, Wisconsin to investigate the pollution by industrial waste the water supply of that city.

Acting Asst. Surg. G. M. CONVERSE, detailed *by* the President for duty in Europe under Surgeon Cumming to investigate sanitary conditions at ports from which troops will be returned.

Pharm. F. J. HERTY, proceed to the Marine Hospital, Baltimore, Md., for temporary duty.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

DISTRICT OF COLUMBIA

Personal.—Dr. L. M. Hynson is absent from the city on a belated vacation.——Lieut.-Col. E. G. Seibert was home recently on furlough from Mineola, L. I.

New Superintendent for Garfield Hospital.—Dr. A. W. Smith, for the past year or two superintendent of Garfield Memorial Hospital, will be succeeded the first of the year by Dr. Carl S. Keyser of this city.

Address on War Surgery.—Col. Bailey K. Ashford, M. C., U. S. Army, now attached to the general staff, recently addressed the Medical Society of the District of Columbia on the "Histopathology and Treatment of War Wounds." As Colonel Ashford's duties in France took him to all parts of the front and required his study of methods in vogue at all surgical centers his address was of intense interest and seemed to bring the very atmosphere of the war operating room across the sea to his auditors.

Medical Society Election.—The following officers for 1919 were elected by the Medical Society of the District of Columbia at a meeting held December 4: president, Dr. William Gerry Morgan; first vice president, Dr. Ada R. Thomas; second vice president, Dr. A. R. Shands; recording secretary, Dr. H. C. Macatee; corresponding secretary, Dr. J. Russell Verbrycke, Jr.; treasurer, Dr. C. W. Franzoni. The following were elected members of the executive committee for a term of three years: Drs. A. W. Boswell, Philip S. Roy and Charles S. White. Dr. Morgan in a speech of acceptance of the presidency not only expressed his appreciation of the honor involved, but announced his intention of using every endeavor to carry to completion the erection of a home for the medical society. This is a project begun under the presidency of Dr. E. Y. Davidson about two years ago; in spite of the deterrent effect of the war, steady progress has been made in paying for a building site, and there is every reason to believe that the year 1920 will see the society in possession of a home of its own. A very interesting and pleasing incident of the same meeting was the reelection of Dr. C. W. Franzoni as treasurer for his forty-fifth term; the society instructed the secretary to cast the unanimous ballot of the society for Dr. Franzoni and adopted the resolution by a rising vote.

ILLINOIS

Chicago

Personal.—Dr. Edward F. Garraghan has been appointed attending laryngologist at Cook County Hospital, to succeed Dr. Joseph C. Beck, who is at present commandant of the Czecho-Slovak Hospital in Cognac, France.

Tuberculosis Institute Luncheon.—The Chicago Tuberculosis Institute gave a luncheon at the Hotel LaSalle, December 11, at which Dr. Robert H. Babcock, Chicago, presided, and Dr. Donald B. Armstrong, Framingham, Mass., gave an account of the Framingham Community Health and Tuberculosis Demonstration.

Illegal Practitioner Fined.—Dr. Bertha C. Day Raymond of 2675 East Seventy-Fourth Street was arrested by the Department of Registration and Education of the State of Illinois, December 3, on the charge of practicing medicine without a license. She pleaded guilty in the municipal court of Chicago and was fined $25 and costs.

Work Against Drug Traffic.—Indictment of seven alleged dealers in opium and morphin were returned by the federal grand jury, December 6. The indictments were secured by Assistant United States Attorney Epstein, under the Harrison Drug Act, which provides a penalty of five years imprisonment or $2,000 fine. The men indicated are as follows:

Wesley S. Johnson, New York, arrested with 30 ounces of morphin sulphate in his possession.

Thomas Cross, known as "Safety Deposit Tom," because he kept his drugs in various banks; recently served two years in Leavenworth, and now arrested as Johnson's chief aid.

Charles Brown, 644 Narth La Salle Street; an old offender peddling drugs in the north side resorts.

Albert Trilling, nicknamed "Ciggie," concealing drug.

Louis Christian, alias "Whitey," smuggler of drug into the Bridewell through aid of women.

Clarence Safford, also a notorious peddler.

Samuel Shields, an exconvict and drug peddler.

The indicted men are said to have had the city divided into districts for the sale of morphin to drug addicts.

LOUISIANA

State Board to Have Its Own Building.—The state board of health has purchased the property at 422 Chortes Street, opposite the New Orleans Court House, to be used as an annex to the board offices. The building will be romedeled and a laboratory is to be constructed on the roof.

Demobilization Resolutions.—At the meeting of the Orleans Parish Medical Society, November 25, resolutions were adopted petitioning the secretaries of the Army and Navy to consider the shortage of medical men on account of the war needs prior to the signing of the armistice, and the presence and recrudescence of influenza, with the object of demobilizing as expeditiously as may be consistent with the efficiency of the service, as many as possible of the medical officers in camps in this country and abroad.

MARYLAND

Released from Hun Camp.—After being interned in a prison camp at Rastatt, Germany, for nearly six months, Capt. Charles W. Maxon, Baltimore, has been released and has reached the American lines. He states that he was well treated, but said that the Germans were greatly in need of physicians, which condition prolonged his confinement.

Slight Increase in Influenza.—The report of fifty-three new cases of influenza during a period of twenty-four hours showing an increase of twenty-nine compared with the record for the previous twenty-four hours, led Health Commissioner Blake to sound a general note of warning. He states that the situation is not alarming and that all of the cases are mild ones, but warns the public to avoid going recklessly into crowded places as this causes the disease to spread.

Many Wounded Soldiers Arrive at Fort McHenry.—A contingent of 256 soldiers arrived at General Hospital No. 2, Fort McHenry, from overseas, via Newport News. An extra force was added to the receiving ward to tally the records and names of the men. Last week 150 or more men arrived at the hospital from overseas and this week two shipments were received, one of which consisted of 146 men from Newport News, and a contingent of 140 wounded from Hoboken. A majority of these are orthopedic cases and represent a more serious type of wound than the military physicians have been receiving. It is expected that patients will arrive until the hospital is filled to its capacity which comfortably accommodates approximately 1,400 men.

MASSACHUSETTS

Hospital in Nantucket.—The Underwood Memorial Hospital, Nantucket, erected by H. O. Underwood, Belmont, in memory of his wife, has been completed at a cost of $50,000 and given to the town of Nantucket.

Personal.—Fred W. Archer, Boston, has been appointed a member of the State Board of Registration and Pharmacy, to succeed William S. Beyary, Melrose.——Dr. Roscoe D. Perley, Melrose, and Dr. Frank S. Bulkeley, Ayer, have been appointed medical examiners (coroners) for Middlesex County.——Dr. John B. Beebe, Great Barrington, has been appointed medical examiner (coroner) and Dr. Clifford S. Chapin, Great Barrington, assistant medical examiner (coroner) for Berkshire County.——Dr. Joseph C. E. Tasse, Worcester, who has been seriously ill at his home for five weeks, is reported to be improving.

MONTANA

Personal.—Dr. Paul A. Remington, for six years assistant surgeon at the Northern Pacific Beneficial Association Hospital, Missoula, has been appointed chief surgeon of the Northern Pacific Hospital, Tacoma, Wash., the largest maintained by that association, and took charge, September 10, succeeding Dr. Saxe W. Mowers.

Hospital Items.—The new hospital erected by the State University of Montana, at Missoula, at a cost of $7,000, for the use of the S. A. T. C., with accommodation for fifty patients, is now completed. The building is 128 feet wide, and 20 feet in depth, and has four wards, and an isolation ward, beside the necessary offices and service rooms.——The Isolation Hospital, Anaconda, recently completed at a cost of

$11,000, was opened to receive visitors, November 23. The building is in the form of a maltese cross, the administration room being in the center, the arms of the cross forming four isolated wards, each containing accommodation for six patients.

NEW YORK

Weiss Found Not Disloyal.—Dr. George C. Weiss, Mount Vernon, formerly health commissioner of that city, was placed on trial, November 25, for a second time, charged with violation of the espionage law, and was found not guilty. In the first trial the jury disagreed.

Personal.—Dr. Mary T. Greene, Castile, has been appointed a member of the Board of Child Welfare, for Wyoming County, to succeed Dr. Henry E. Pierce, deceased.——Dr. William G. Bissell, Buffalo, on November 21, was elected president of the state board of medical examiners.——By unanimous vote of the city council of Niagara Falls, the bill of Health Officer Scott for $603 due him as registrar of vital statistics was ordered paid.

Hospital Directors Elected.—At the annual meeting of the directors of the Elizabeth A. Horton Memorial Hospital held in Middletown, N. Y., November 25, Dr. Theodore D. Mills, Middletown, was elected president of the corporation which will have charge of carrying out the terms of Eugene Horton's will, regarding the erection of a hospital in memory of his mother and for which he provided a fund of $600,000. Dr. Daniel B. Hardenbergh, Middletown, was also elected a director of the corporation. A committee was also elected to select a site for the institution.

New York City

County Society Election.—At the annual meeting of the Medical Society of the County of New York, held November 25, the following officers were elected; president, Dr. Charles Howard Peck; vice presidents, Drs. Charles H. Chetwood and George Gray Ward, Jr.; secretary, Samuel S. Dougherty; assistant secretary, Dr. J. Milton Mabbott, and treasurer, James Peterson.

Resolutions Regarding Major Bissell.—The executive committee of the Medical Board of Bellevue Hospital, at a meeting held December 3, adopted a resolution setting forth its profound sorrow and regret at the death of Major Joseph Biddleman Bissell, M. C., U. S. Army, chief of the surgical service at Fort McHenry, Md., and visiting surgeon and surgical director of the fourth division of Bellevue Hospital.

Academy of Medicine Elects.—At its anniversary meeting, December 5, the New York Academy of Medicine elected the following officers: president, Dr. George David Stewart; vice presidents, Drs. Reginald H. Sayre and Charles H. Peck; recording secretary, Dr. Royal S. Haynes, and trustee, Dr. Walter B. James. Lieut.-Col. Raffaele Bastianelli, professor of surgery of the University of Rome, was elected to honorable fellowship in the academy.

Injunction Asked.—A permanent injunction has been asked by the head of the Flatbush Chamber of Commerce, restraining the city officials from reopening the Barren Island garbage plant. The argument was supported by an affidavit from the president of the board of trustees from Bellevue and Allied Hospitals, after having discovered the effect that the noxious odors from the garbage plant have had on the patients in the Hospital for Crippled Children, which is located on Rockaway Peninsula.

Life Insurance Presidents Meet.—The Association of Life Insurance Presidents which met at the Hotel Astor, last week, listened to a paper by Major-Gen. William C. Gorgas, read by William D. Wrightson, in which were pointed out the lessons in sanitation that the soldiers of the United States have gained in their camp life. He expresses the conviction that when these men return home they will be desirous of applying these same measures to their home communities in so far as such application is possible. In his opinion the greatest sanitary lesson of the war is the effect of crowding in large units. He suggests that both overcrowding and segregation might be avoided by constructing the cantonments of huts 20 feet by 20 feet in plan containing not more than six men. He believes that the death rate from disease in our Army in this war will be far less than the best death rate that has gone before us—it will probably be somewhere near 9 per thousand up to October 1. After that date there will be an increase over this figure owing to the appearance of influenza in the camps. Another paper presented by Dr. Frederick L. Hoffman on compulsory health insurance showed that this measure had proved a complete failure as a function of the state in Germany.

NORTH DAKOTA

Personal.—Dr. Oliver E. Distad, Williston, who started for China in October and was taken ill with pneumonia at Seattle, sailed for China, November 22.——Dr. A. G. Long, recently appointed acting director of the public health laboratory at the University of North Dakota, Grand Forks, has assumed his new duties. He succeeds Dr. John W. Cox, University, resigned.——Dr. Joseph T. Newlove has been appointed health officer of Minot, to succeed vice Dr. Harry G. Knapp whose term has expired.

OHIO

Protest Against Reduction.—Dr. Walter E. List, superintendent of the Cincinnati General Hospital, has made a protest to Financial Director Holmes against the reduction of $22,000 in the appropriation for the hospital for 1919, as compared with the amount appropriated for 1918.

Physicians' Offices Closed.—The Mayor of Warren, November 25, issued a proclamation ordering the closure of all physicians' offices during the prevalence of influenza. For the time being, excepting emergency cases, persons who desire to consult physicians can see them only by appointment.

Fund Allotted for Health Board.—The United States Public Health Service announced, November 20, that the sum of $51,832.61 had been allotted by the federal government to the state of Ohio, for the use of the department of health in that state, for the prevention, control and treatment of diseases.

To Improve Rural Health Protection.—The legislature will consider plans for reforming the administrative health machinery in small local districts, as the rural districts and small towns of the state are not giving adequate health protection under the existing laws. It is proposed to group the health districts of the state into larger units, and thereby to provide means of employing a sufficient number of competent health workers.

Personal.—Dr. Earl A. Martin, superintendent of the Cincinnati Tuberculosis Sanatorium, resigned, November 30, resignation to take effect as soon as a successor is appointed. Dr. Martin expects to enter the mission field as a medical missionary.——Dr. Oscar H. Sellenings, Columbus, who has been engaged in child welfare work in France under the auspices of the American Red Cross, with headquarters at Marseilles, has returned to the United States.——Dr. Charles B. Finefrock, Port Clinton, has been appointed coroner of Ottawa County, to succeed Dr. Mason J. Skiff, Oakharbor, who has resigned.——Dr. Martin F. Vereker has been elected health officer of Hamilton.

Deprecate Child Labor.—The state department of health and state council of national defense have united in a drive to keep children out of industrial occupation and in school. The officials dwell on the responsibility of communities to provide scholarships or other aid for children financially unable to continue in schools, and on the necessity of teachers making schools attractive to the children. During the war the growing tendency toward the employment of child labor was noted and while the government refused to sanction the employment of children in war work, nonessential industries were beginning to look on children as the reservoir of cheap labor. The war time labor situation had not demanded the employment of children, and with the close of the war the employment of children becomes still more inexcusable.

PENNSYLVANIA

Gift of Scholarship.—The Pennsylvania Training School for Feebleminded Children eventually will receive $5,000 for the maintenance of a scholarship from the estate of the late Benjamin H. Smith.

Venereal Dispensary Opens.—The Department of Health of the Commonwealth of Pennsylvania announces the opening of a genito-urinary dispensary in Shenandoah, under the charge of Dr. Christian Gruhler. The dispensary is open on Tuesdays and Fridays from 8 to 10 p. m.

Personal.—Dr. William H. Emery, Coatesville, while driving from his home toward Downington, November 29, lost control of his car and crashed into a telegraph pole. The machine was demolished and Dr. Emery was taken to the Chester County Hospital suffering from concussion of the brain and serious cuts and bruises.——Dr. Henry J. Bell, Pittsburgh, was attacked by robbers, November 26, and beaten and robbed.

Philadelphia

Receive New Professors.—The Medical Club of Philadelphia gave a reception at the Bellevue-Stratford Hotel, December 13, in honor of Dr. Jay F. Schamberg and Lieut.-Col. J. Torrance Rugh, M. C., U. S. Army, newly elected professors in Jefferson Medical College.

Staff Election.—The staff physicians of St. Mary's Hospital at their meeting, November 23, elected the following officers: Dr. Joseph H. Ross, president; Dr. Louis F. Love, vice president; Drs. William P. Grady and George C. Kieffer, secretaries, and Dr. Ellwood R. Kirby, medical director.

Personal.—Dr. Collin Foulkrod has been elected to fill the vacancy on the staff of the Maternity Hospital caused by the death of Clarence H. Gray.——Major Jackson Stewart Lawrence, M. R. C., attached to the 368th Infantry, colored regiment, was given the distinguished service cross, the highest field honor for bravery, by General Pershing, for saving the life of a negro soldier without regard for his own safety.——Capt. Thomas C. Ross, in command of Ambulance Company No. 110, 103d Sanitary Train, was wounded early in September while giving aid to the wounded under fire.——Dr. William T. Shoemaker, who went to France with Base Hospital No. 10 from the Pennsylvania Hospital, has been made consulting ophthalmologist to all American hospitals in England. Dr. Shoemaker's appointment carries the rank of lieutenant-colonel.

Reconstruction Conference.—A conference under the auspices of the Division of Hygiene and Engineering of the Department of Labor and Industry was held at the Bellevue-Stratford Hotel, December 6. Representatives of the National Association of Industrial Physicians and Surgeons, from all sections of the country, are holding their seventh annual conference in conjunction with the labor and industry meeting. Dr. Francis D. Patterson, Harrisburg, chief of the Department of Hygiene and Engineering of the Department of Labor and Industry, presided. Problems of physical reconstruction and industrial rehabilitation of war and industrial cripples were considered. Major R. Tait McKenzie, formerly of the British army, now director of physical education at Pennsylvania University, read a paper on "Mechanical Aids to Reclamation"; Dr. Alfred Stengel read a paper on "The Reclamation of the Diseased," and T. B. Kidner, vocational secretary of the Invalided Soldiers' Commission of Canada, read a paper on "Vocational Training for the Handicapped."

WASHINGTON

Personal.—Dr. Jerry E. Vanderpool, health officer of Walla Walla and Walla Walla County, resigned, November 30, his resignation to be effective as soon as a successor can be named.

WISCONSIN

Smallpox in Oshkosh.—It is announced that eleven cases of smallpox have been discovered at Oshkosh, seven of which were at first diagnosed as influenza. The seven houses in which these cases were found have been placed under strict quarantine.

College Raised Its Million.—The Marquette University of Milwaukee has succeeded in raising its medical school endowment fund of $1,000,000, one-third of which was donated by the Carnegie Foundation for the Advancement of Teaching. The income from this fund is to go for the salaries of teachers and maintenance and cannot be used for buildings, additional funds for which are now being sought.

Antituberculosis Society Meeting.—The annual meeting of the Wisconsin Anti-Tuberculosis Association was held in Milwaukee, December 13 and 14. The essential subject of discussion at this meeting was the establishing of free and pay tuberculosis clinics in every suitable county in the state. A public health program for the ensuing year was also presented which gave particular emphasis to tuberculosis. The changed conditions, and in particular the uncovering of a large number of cases of incipient tuberculosis in discharged soldiers and draft rejects, have convinced the association that the next link to be formed in the chain of defense against tuberculosis is the dispensary.

CANADA

Plans New Medical Building.—The Faculty of Medicine of Western University, London, Ont., is planning the erection of a new medical college building at an estimated cost of $100,000.

Personal.—Major Thomas D. Archibald has been transferred from the command of the Whitby (Ont.) Military Hospital to the new St. Andrews Military Hospital, Toronto.——Capt. Fred G. Bantling, M.B., Alliston, Ont., is reported to have been wounded.——Dr. Walter S. Downham, who has been acting medical officer of health, London, Ont., since the resignation of Dr. Hibbert W. Hill, has been recommended by the board of control for permanent medical officer of health.

Hospital News.—New regulations have been adopted by the board of governors of the Kingston (Ont.) General Hospital for the reorganization and extension of the visiting staff. The idea is to to make the institution a teaching hospital in connection with Queen's University Medical Department.——The Canadian Hospital ship *Araguya* has begun its tenth voyage to Canada. It is in command of Col. D. A. Whitton, Ottawa.——The Board of Control, Toronto, has recommended a grant of $16,000 for the Hospital for the Incurables.——The new Orthopedic Military Hospital in Toronto will be opened early in 1919, and it is proposed to use it for teaching purposes as well as being the central orthopedic hospital for soldiers in Canada. It is to have accommodation for from 1,500 to 2,000 patients.——The Toronto Free Hospital for Consumptives is seeking a grant of the Toronto Board of Control of $31,000 to clear off the deficit engendered during the last hospital year.——The reception hospital in Toronto has been inspected and reported on by the medical officer of health, Dr. Charles J. C. O. Hastings. He finds that the building is old and dilapidated, and totally unfit for purposes for which it is used. Here have been watched incipient cases of insanity, and it looks as though the city will have to provide better accommodation.

Ontario Medical Practice Act.—The government called the various cults and the representatives of the medical fraternity in Ontario last week for the purpose of discussing the report of the commissioner, Mr. Justice Hodgins. The medical profession was satisfied with the report in general, but proposed, or suggested, the following definition of the practice of medicine: "The practice of medicine shall mean and include the diagnosis, healing, alleviation or attempt to diagnose, treat or relieve any ailment by advice, assistance or any means with or without the use of drugs or mechanical means." The osteopaths thought they should be given a department in the universities of the province, and the power to appoint the instructors in anatomy and physiology. The minister of education asked what a speaker for that body meant when he referred to osteopathic anatomy and scientific anatomy; what was the difference? The reply was that osteopathic anatomy was the scientific anatomy. Col. Alexander Primrose, C.M.G., Toronto, president of the Academy of Medicine, told of his observations in England and France where neither the British nor Canadian forces allowed any one but a qualified surgeon or physician in the C. A. M. C. and the R. A. M. C., as they had specially trained physicians and surgeons for all branches of manipulative surgery. He advised the government to inquire into his statement.

GENERAL

Gorgas in New Activities.—Major-Gen. William C. Gorgas, M. C., U. S. Army, retired, who recently returned from France, will undertake work as director of war field work for the Rockefeller Foundation and will soon sail for Central and South America.

American Association for the Advancement of Science.—The seventy-first meeting of the American Association for the Advancement of Science will he held in Baltimore, Dec. 23 to 28, 1918. The opening general session will be held in McCoy Hall, 311 West Monument Street, December 26, when Dr. Goodnow, president of Johns Hopkins University, will deliver an address of welcome, and Dr. Theodore Richards of Harvard will speak on the conservation of the world's resources. Regular meetings of the sections will be held from Thursday morning, December 26, to Saturday, December 28.

Division of Industrial Hygiene and Medicine.—Physicians, sanitarians and nurses who are desirous of establishing industrial connections may now register for this purpose with the Division of Industrial Hygiene and Medicine. This division, with personnel detailed by the United States Public Health Service, is acting for the Working Conditions Service of the Department of Labor in the investigation and supervision of the health of industrial workers. In connection with these activities the division proposes to carry on a service whereby employers who wish to obtain medical personnel for their establishments may be put in touch with available physicians, sanitarians and nurses. To facilitate this service a register will be kept by the division, and physicians, sanitarians and nurses desiring to become affiliated with industrial establishments are asked to communicate with the Division of Industrial Hygiene and Medicine, 202 Ouray Building, 805 G Street, Northwest, Washington, D. C., mentioning qualifications, type of industrial connection preferred and salary expected.

Poliomyelitis Report.—The Public Health Service has recently published a report of epidemiologic studies of poliomyelitis occurring in 1916 in New York City and northeastern United States, with intensive studies of the disease in certain cities and counties in New Jersey, Connecticut and Rhode Island. Present knowledge in regard to the epidemiology of poliomyelitis is summarized. The publication is *Public Health Bulletin 91*, by Drs. Claude H. Lavinder, Staten Island, N. Y.; Allen W. Freeman, Columbus, Ohio, and Wade H. Frost, Washington, D. C. Another bulletin of interest from the Public Health Service is *Public Health Bulletin 95*, by Dr. Joseph G. Wilson, New York City, on infectious diseases in children, the study covering about 6,000 cases among immigrant children. The main conclusion reached as the result of this study is that it is practicable to treat contagious and noncontagious diseases in the same hospital and with the same nursing force, and even in the same wards provided the wards are cut up into small cubicles and the proper nursing technic is enforced. There is practically no danger of cross infection.

Influenza.—While a number of communities throughout the United States report the subsidence of influenza and the removal of restrictions, since the last week in November there has been a notable recurrence of the outbreak in a good many states. In many instances it has been found desirable to return to the restrictions with reference to public gatherings, schools, churches, amusements, etc., and in a number of places masks are required in public places. In most instances, it is believed, the disease is not so severe in its nature and the death rate is lower than in the first intense wave of the epidemic, and with the education gained by the public in the former wave less trouble is experienced in handling the disease. Indiana is one of the states which seems to be hit hardest by the recrudescence. Ohio also reports many new cases throughout the state, but with a percentage of fatalities running only about one half that of the earlier outbreak. It is the hope of the authorities in that state that by precautionary measures among the 40 per cent. of the people susceptible to the disease it may be strung out over as long a period as possible, thus causing less disruption of the ordinary routine of business and life in general. Wisconsin, Kansas, Michigan, New York state and Illinois, particularly Chicago, report general increases in the number of cases. *Public Health Reports*, November 29, continues the publication of state summaries of the disease. It is probable that a number of cases of influenza above the normal endemic figures will continue throughout the winter, with a considerable number of pneumonia cases, the regular season for which is just beginning. At the meeting of the American Public Health Association in Chicago during the present week influenza was one of the important topics of discussion.

FOREIGN

Malaria Control on the Island of Cyprus.—On the island of Cyprus an antimalaria campaign has been in progress since 1913. In the annual medical report for the island for 1917 it is said that the number of persons with malaria treated was reduced from 10,035 in 1912 to 2,709 in 1917, and the percentage of large spleens in schoolchildren was reduced from 17.2 in 1913 to 6 in 1917. The work has consisted in cleaning and improving drains and streams, making new drains, filling in, screening or covering wells, stocking wells with fish, filling in or draining pools, cutting and removing grass, etc. Drugs were used to some extent.

CORRECTION

Influenza at Rome.—The Journal of August 17, in describing the measures taken against influenza in Europe, mentioned the closing of the schools and moving picture shows at Rome. The *Policlinico* commented later on this, that "contrary to the usual accuracy of The Journal, this news item was without foundation," adding, "And this is the way history gets written." The news item was taken from a foreign journal, but it seems that last summer the epidemic was too mild at Rome for such strenuous measures. The November numbers of our Italian exchanges, however, relate that these very measures were being enforced at Rome at date of writing. History got itself written too previously, it seems, but the facts finally managed to catch up with it.

BUENOS AIRES LETTER

Buenos Aires, Oct. 26, 1918.

Epidemic of Influenza

The steamships *Demerara* and the *Infanta Isabel* arrived at Buenos Aires with numerous cases of influenza on board, and there had been several deaths during the voyage. The public health authorities allowed the passengers to disembark without taking any prophylactic measures whatever. Fifteen days later numerous cases of influenza developed in the city, especially in the mail service, in which there were over 100 cases in one day. By another week the infection had spread throughout the entire city thence to numerous points in the interior of the country. It is estimated that there have been 250,000 cases in Buenos Aires alone. Fortunately the disease has been of a mild type, no deaths occurring except nine fatal cases in the Hospital Muñiz. Quite recently the mortality has increased a little, but it is still low. The symptoms are generally headache, pains in the muscles, sore throat, high fever and prostration. In the majority of the cases improvement is evident by the second to the fifth day, but pronounced depression and anorexia are left. The graver cases developed pulmonary or gastro-intestinal symptoms. Almost all the fatalities were from pneumonia or bronchopneumonia. The Pfeiffer bacillus was encountered in most of the cases examined. In the pneumonia cases, it was associated with the pneumococcus.

The indecision of the public health authorities has been the object of much criticism. The Departamento Nacional de Higiene has been without a head for several months.

Infantile Mortality

Under the auspices of the Sociedad Argentina de Pediatria three special meetings have been held to discuss problems relating to infantile morbidity and mortality in Argentina. In the last few years they have presented a certain increase. The mortality of children less than a year old represents 21 per cent. of the total mortality. The figure in reality is low in the capital and on the coast, but it is considerable in the provinces of the interior. It was decided to appoint a special committee to advise the most important measures to be taken.

The University Elections

The curious reform in the statutes of the universities, which has recently received official sanction, accords to the students the right to vote for the election of the dean and of the members of the Consejo Directivo de las Facultades, the voting delegates from the students to equal in numbers the number of the regular professors of the various faculties. These new conditions have led to an extraordinary electoral agitation. The students have made out lists of candidates whom they expect to elect. They are solidly backing all persons known to be opposed to the present university authorities, and those who for any reason they think have been victims of injustice. Sensible persons are hoping that this reform will not last long.

LONDON LETTER

London, Nov. 19, 1918.

The Influenza Epidemic

Though fresh cases of influenza continue to occur, the epidemic has spent its force and the number of patients under treatment has greatly diminished. The complication of pneumonia is less often fatal than it was at first. The Royal College of Physicians has drawn up a memorandum for the information of the public. It is pointed out that the present epidemic is virtually world-wide, irrespective of race, community or calling. Similar world-wide epidemics occurred in 1803, 1833, 1837, 1847 and 1890. The long intermission since the last widespread epidemic had made an early reappearance probable, but the conditions of epidemic prevalence of influenza are too obscure to allow of precise prediction. This outbreak is essentially identical, both in itself and in its complications, including pneumonia, with that of 1890. The disproportionate occurrence of a special symptom, a well-recognized phenomenon in the case of epidemics, for example, nosebleed in the present epidemic, does not invalidate this statement. The nature of the virus is still uncertain. It is possibly beyond the present range of microscopic vision. The bacillus discovered by Pfeiffer has in the past been regarded as the probable cause, though on insufficient evidence. There is no doubt as to the primary part it plays in the disease, important though it probably is as a secondary infecting agent. Pfeiffer's bacillus, the pneumococcus, and, above all, in this epidemic the streptococcus, seem to be responsible for most of the fatal complications of influenza. Infection is conveyed from the sick to the healthy by the secretions of the respiratory surfaces. In coughing, sneezing, and even in loud talking, these are transmitted through the air for considerable distances in the form of a fine spray. The channels of reception are normally the nose and throat; hence the importance of avoiding thronging of every sort. The period of incubation is about forty-eight hours, or even somewhat less. Good nourishing food, and enough of it, is desirable. War rations are fully adequate to the maintenance of good health, though they may not afford just the particular articles that each fancy demands. Alcoholic excess invites disaster; within the limits of moderation each person will be wise to maintain unaltered whatever habit experience has proved to be most agreeable to his own health. As the primary cause of influenza is unknown, no form of inoculation can be guaranteed to protect against the disease. Moreover, the lack of enduring protection after an attack shows that a vaccine could not protect for more than a short period. No drug has as yet been proved to have any specific influence as a protective.

Medical Demobilization

The Central Medical War Committee has recommended that medical officers who have served away from the area of their practices since the beginning of the war should be released before others serving temporarily with the forces. The Ministry of National Service has advised that this principle be adopted, and the Army Medical Department has agreed that officers who have served since the beginning of the war shall be released first from the army, while those who have qualified since the war began shall be withdrawn last.

Barbarities Committed by German Physicians

In the House of Commons, Sir George Cave, the home secretary, who recently went on a mission to Germany to arrange for the exchange of British for German prisoners, referred to the cruelties perpetrated on British prisoners in the camps and salt mines and those employed behind the lines to dig trenches and set up wire. He also said: "There are others, even in the hospitals, where, surely, humanity ought to reign. No doubt there are many humane physicians in Germany, but there are others who make a cruel distinction between British prisoners and other prisoners of war; and even among nurses many are found, who, far from helping suffering prisoners, have stooped to inflict insult and injury on them. The hospitals, as is shown by the condition of our men who are arriving in Holland and Switzerland, are in a very bad state, and our wounded do not get proper treatment." As previous letters to The Journal have shown, this conduct of the German medical profession is far from exceptional. In a letter to the *Times*, Mrs. Vincent Smith gives a harrowing account of the treatment of her aged father, Colonel Baddeley, British consul at Bruges, who after enduring all sorts of persecution in his house was taken to Germany. When he arrived at Aix-la-Chapelle his condition so aroused the pity of the Red Cross women that one brought him some soup, but a physician nearly knocked the cup out of her hand and asked her what she meant by having pity on an Englishman, and ordered the sentries to take him away. The same physician later came on the station platform and collected a crowd and cursed the old gentleman and his daughter in English. When they arrived at the camp at Giessen there was one physician who was " a good sort," but another, a professor, a perfect brute. He told the Red Cross men they were never to speak to Mrs. Smith or to do anything for her or to give her medicine.

Penalty for Soldiers Refusing to Submit to Treatment

In the naval and military war pensions bill, which is now passing through the House of Commons, there is the following clause: If any disabled officer or man, on being so required in the prescribed manner, refuses or without reasonable cause fails to submit himself for medical examination, or if any disabled officer or man, as respects whom it has been certified that treatment in an institution or otherwise is necessary in his interest, refuses or without reasonable excuse fails to undergo such treatment in accordance with such directions as may be given in that behalf by or with the approval of the minister, the minister may, if he thinks fit, order that any pension or allowance to which that officer or man would otherwise be entitled shall cease to be payable either in whole or in part for such period as may be specified in the order. Mr. Hodge, minister of pensions, said that there was power to punish a man to the extent of withholding half his pension if he refused treatment; but if a man's pension was taken away, the punishment, if he was a married man, fell on his wife and child. He hoped that the power asked for under the bill would of itself be sufficient to induce men to accept treatment.

Rations for Tuberculous Persons

A new dietary scale for the tuberculous has been issued by the government. The following are the maximal weekly amounts for each male over 10 years of age residing in a sanatorium or special ward set apart for the treatment of tuberculosis: meat (including suet) 56 ounces; fish and poultry, 16 ounces; bacon, 8 ounces; bread, 64 ounces; flour, 8 ounces; sugar, 8 ounces; butter and margarin, 10 ounces; lard and edible fats, 3 ounces; potatoes, 80 ounces; vegetables (fresh), 28 ounces; milk, 14 pints; jam, syrup, etc., 8 ounces; cereals, 12 ounces; oatmeal, 8 ounces; peas, beans and lentils, 8 ounces; tea, 2 ounces, and cheese, 4 ounces. Since patients suffering from marked constitutional disturbance may be unable to take peas, beans and lentils or the full amounts of potatoes and bread specified, an adult male patient certified by the medical officer of the institution to be so suffering and to require additional milk shall be entitled to not more than 7 pints of milk weekly (or the equivalent in dried milk prepared from whole or separated milk) in addition to the amount specified. Females over 10 years of age and children under 10 are entitled to four fifths and three-fifths, respectively, of the amounts laid down for males over 10, except that in every case the patient will be entitled to 8 ounces of sugar and 3 ounces of edible fats weekly.

Prostituted Science

In his presidential address to the Faraday Society, Sir Robert Hadfield said that the war had been largely one of the metallurgist, the engineer and the chemist. To the enemy scientists had been left the ignoble rôle of prostituting knowledge to the basest of uses. No matter how clever had been their inhuman ideas with regard to poison gas, petrol flame throwers, etc., the enemy's men of science in time to come would look back and find everything to be ashamed of and nothing of which they could be proud. On the other hand, the scientific men of all the Allies had not only clean hands but also clean minds. While it had been necessary for us in self defense to meet and counterattack the many horrible devices of the enemy, there was not a man in the whole of the British Empire who would have introduced one of these terrible devices. Huns of all classes were equally to blame for this war. Of what use, therefore, was it to talk about a league of nations at this hour of the day? It would be a league of fools if it included Germany after her unparalleled atrocities, inhumanity and bestiality. To admit the Hun to any council of nations would be like inviting a burglar or a murderer to join a Y. M. C. A. council.

PARIS LETTER

Paris, Nov. 14, 1918.

Prophylaxis and Treatment of Complications of Influenza

At a recent meeting of the Académie de médecine, Dr. Louis Weiller recommended the use of dilute solutions of beechwood creosote in the prophylaxis and treatment of the pulmonary complications of influenza. Every twelve hours the patient is given in an enema a glass of lukewarm milk containing about 1 drop of creosote for each year of age for children, and 25 to 30 drops for adults. The mixture should be well shaken and the enema retained for at least two hours. In cases of pulmonary complication, the dose should be increased by 2 to 5 drops for children and 4 to 8 drops for adults. The complication subsides rapidly. The intervals should be lengthened when the temperature becomes normal, and two days after the cessation of the pyrexia, the treatment is stopped. Albuminuria, so frequent a symptom in pneumococcic infections, is not a contraindication for this treatment. As adjuvant medication, acetate of ammonia may be given by mouth, and antisepsis of the nasopharynx should not be overlooked.

The Influenza Epidemic

The epidemic of influenza is on the wane in Paris. For the week ending November 2, 1,119 deaths from influenza were registered as against 1,263 for the preceding week. Adding to these figures the deaths caused by acute diseases of the respiratory apparatus, the result is 1,539 deaths as against 1,778 for the preceding week. M. Mesureur, directeur de l'Assistance publique, reports that the hospital admissions have fallen off about 50 per cent., and the wards are no longer crowded with patients.

Dr. Louis Mourier, undersecretary of state for the Service de Santé militaire, reported to the Commission d'hygiène that in the army the epidemic is subsiding, and that most of the cases of today do not present the gravity met with formerly.

Letter from General Petain to the American Red Cross

General Petain, commander in chief of the Armies of the North and Northeast, addressed a letter to Colonel Gibson, commissioner for France of the American Red Cross, in which he acknowledged receipt of the notice that the American Red Cross had voted a new credit of 10 millions for the relief of French soldiers and officers, and extended his personal thanks and the thanks of the armies under his command for this kindness. He made acknowledgment of the valuable moral and material aid rendered by the American Red Cross, and did not fail to extend his appreciation to the people of the United States as a whole.

Interallied Social Hygiene Congress

The Comité national de l'éducation physique et de l'hygiène sociale, presided over by M. Henry Paté, has decided to organize, with the assistance and under the patronage of the government, an interallied congress of social hygiene, whose object will be the reconstruction of the devastated regions. This congress will be held in Paris early in 1919, and will have an interallied social hygiene exposition.

Office of Food Controller

The under-secretary of state of provisioning has established a food controller's office for the purpose of facilitating the work of the authorities in regulating prices, and in securing and distributing food to the civil population, calling to its assistance experts on syndical organizations, sales and production.

Making Tuberculosis a Reportable Disease

The matter of making tuberculosis a reportable disease having again been made a subject for discussion by the public authorities, the Conseil d'administration du Syndicat des médecins de la Seine, has issued the following statement: "The Conseil d'administration believes that it is absurd to make tuberculosis a reportable disease before ample proper means for treating these patients have been provided (dispensaries, sanatoriums, special hospitals, farm colonies, etc.). The compulsory declaration of the disease, to which the Syndicats médicaux have on numerous occasions made objection, is not even justified by the usefulness of the disinfection, made by order of the law, of the home of the patient. Such disinfection is of value only when made at the time the patient leaves the domicile. Applied under any other conditions, the tuberculous patient becomes an object to be dreaded, an outcast, and this disinfection, moreover is inefficacious. The only effectual disinfection is that done by the patient or those around him, repeated every day; all these persons must be instructed in hygiene in this line. Tomorrow as well as today, the attending physician will apply only the measures taken in the interest of the patient and his family, and he will not have any respect for administrative decisions or ordinances which may conflict with one or the other."

American Red Cross Hospitals in Vicinity of Paris

Military Hospital No. 7 of the American Red Cross has been opened at Malabry near Plessis-Robinson, about ten kilometers from Paris. The hospital is placed in a park by permission of the département de la Seine, valid for the duration of the war. The hospital opened with about 600 beds. The American Red Cross now maintains in and around Paris seven hospitals: the former American Ambulance at Neuilly; the hospital of Dr. J. A. Blake; the hospital of the Whitelaw Reids; the military hospital of Joinville-le-Pont; the Auteuil hospital; the Neuilly hospital for diseases of the skin, and the new Malabry hospital.

Donation to Academy of Medicine

Dr. Dragovitch has donated to the Académie de médecine bonds of the value of 2,000 francs, bearing 5 per cent. interest, for the purpose of founding two prizes, one for the best work on the etiology and treatment of mental diseases, and the other on the etiology and treatment of diseases of metabolism.

Deaths

Major Joseph Biddleman Bissell ⊕ **M. C., U. S. Army,** New York City, College of Physicians and Surgeons in the City of New York, 1883; aged 59; chief surgeon of U. S. General Hospital No. 2, Fort McHenry, Md.; clinical professor of surgery in University of Bellevue Hospital Medical College; a member of the American Urological Association; for nearly twenty years a member of the surgical staff of Bellevue and St. Vincent's hospitals; consulting surgeon to the Hospital for Deformities and Joint Diseases, and to the German Hospital and Dispensary; surgical director of the Radium Institute of New York, and president of the American Radium Society; died in Mount Sinai Hospital, New York City, December 1, from septicemia.

Lieut. Thomas Jefferson Palmer ⊕ **M. C., U. S. Army,** McAlester, Okla.; University of Illinois, Chicago, 1905; aged 39; a veteran of the war with Spain; who, after a course of training at the Medical Officers' Training Camp, Fort Riley, Kan., was assigned to duty with Field Hospital No. 27, Sixth Division; and sailed for France, June 28; while on duty, September 10, at a French Hospital on the Western Front, was gassed, and died October 28, at Base Hospital No. 14, Bordeaux, France.

John Down Heritage, Glassboro, N. J.; University of Pennsylvania, Philadelphia, 1863; aged 81; assistant surgeon, Eleventh New Jersey Infantry during the Civil War; taken prisoner at the battle at Ream's Station, and afterward confined in Libby Prison, Richmond; in 1873 elected grand chancellor of the Knights of Pythias of New Jersey; died at his home, November 20.

Watson Lovell Wasson ⊕ Waterbury, Vt.; University of Vermont, Burlington, 1901; aged 44; professor of mental diseases in his alma mater; a specialist in psychiatry; superintendent of the Vermont State Hospital for the Insane, Waterbury; died in that institution, November 24, from pneumonia.

James Smith Ford, Loomis, N. Y.; College of Physicians and Surgeons in the City of New York, 1910; aged 32; a member of the Medical Society of the State of New York; senior assistant physician of the Loomis Sanatorium; died in that institution, November 21, from pneumonia following influenza.

Asst. Surg. Bertram L. Cunningham ⊕ **Lieut. (j. g.), U. S. N. R. F.,** Jamaica, N. Y.; New York Homeopathic Medical College, 1913; aged 30; on duty at the Medical Office, Third Naval District Headquarters, New York City; died in New York City, October 21, from bronchopneumonia following influenza.

Lieut. Samuel Dennison Shannon ⊕ **M. C., U. S. Army,** Baltimore; University of Maryland, Baltimore, 1915; aged 26; who entered the Medical Corps in May, 1917, and was later transferred to the British Medical Service, died in the Red Cross Hospital, London, November 5, from influenza.

Capt. James McFarland ⊕ **M. C., U. S. Army,** Burlington, N. J.; University of Pennsylvania, Philadelphia, 1911; aged 31; who entered the service in April, 1917, and after a tour of duty at Camp McClellan, Ala., went to France in June, 1918; died, October 24, from wounds received in action.

Eldora Alice Thomas, Chicago; University of Illinois, Chicago, 1913; aged 33; for several years a medical missionary in Sierra Leone, West Africa; more recently house physician at the University Hospital, Chicago; died in that institution, November 26, from valvular heart disease.

Roy Herman Renn, Williamsport, Pa.; Jefferson Medical College, 1906; aged 40; a member of the Medical Society of the State of Pennsylvania; while hurrying to the train after making a professional call at Nisbet, Pa., November 28, died suddenly from heart disease.

Joseph Felix Corrigan, St. Leo, Fla.; College of Physicians and Surgeons in the City of New York, 1871; aged 72; one of the founders of the New York Foundling Asylum, and for many years house physician at Bellevue Hospital; died at his home, November 28.

Amelia M. Augur, Cooperstown, N. Y.; Northwestern University, Woman's Medical School, Chicago, 1880; aged 62; died in the City Hospital, Binghamton, October 31, as the result of injuries received when she was run down by a motor truck, in Endicott.

Col. Samuel M. Horton ⊕ **M. C., U. S. Army** (retired), Albany, N. Y.; Jefferson Medical College, 1861; aged 80;

who entered the Army as assistant surgeon in 1861, and was retired June 6, 1894, on account of disability in line of duty; died in Albany, recently.

Lieut. Frederick George Carow ⊕ **M. C., U. S. Army,** Brooklyn; Jefferson Medical College, 1917; aged 30; on duty with the One Hundred and Fifty-Second Depot Brigade, Camp Upton, N. Y.; died in the camp hospital, October 16, from pneumonia.

Edward Everett Peck, Caldwell, N. J.; Bellevue Hospital Medical College, 1879; aged 64; a member of the Medical Society of the State of New Jersey; mayor of Caldwell; was found dead in his garage, November 22, from cerebral hemorrhage.

Lieut. LeCount Rochambeau Lovellette ⊕ **M. C., U. S. Army,** Chicago; University of Illinois, Chicago, 1917; aged 25; on duty in the base hospital at Fort Sam Houston, San Antonio, Texas; died at his post, December 2, from lobar pneumonia.

John Gustavus Winkelman, Brooklyn; New York University, New York City, 1879; aged 62; formerly a member of the staff of Kings County and St. Catherine's Hospitals; died at his home, November 24, from heart disease.

Omar Clinton Henry, Minerva, Ky.; Hospital College of Medicine, Louisville, Ky., 1905; aged 37; a member of the Kentucky State Medical Association; died at his home, October 13, from pneumonia following influenza.

Died in the Service
IN FRANCE
Major Shadworth O. Beasley, M. C., U. S. Army, 1876-1918
(See The Journal, last week, p. 1930)

Lieut. Albert Fabian Welin ⊕ **M. C., U. S. Army,** Rio Vista, Calif.; Leland Stanford Jr. University, Palo Alto, and San Francisco, 1915; aged 28; died at Camp Kearney, Calif., October 31, from pneumonia following influenza.

Ralph Almeron Parker, Greene, Me.: Bowdoin Medical School, Brunswick and Portland, Me., 1904; aged 57; at one time a member of the Maine Medical Association; died at his home, October 13, from heart disease.

John Patrick Rowan, Brooklyn; Long Island College Hospital, Brooklyn, 1898; aged 41; a member of the staff of the Brooklyn, St. Peter's, Holy Family, St. Mary's and St. Catherine's hospitals; died, November 27.

Sarah C. Lowry, Portsmouth, Ohio; Laura Memorial Woman's Medical College, Cincinnati, 1896; aged 45; died at her home, Kitt's Hill, Scioto County, Ohio, November 20, from pneumonia following influenza.

Leora Franklin Hicks ⊕ Amo, Ind.; Medical College of Indiana, Indianapolis, 1901; aged 44; on duty at the base hospital, Nitro, W. Va.; died in that institution, October 27, from pneumonia following influenza.

Charles Thomas Amason, Doles, Ga.; Louisville (Ky.) Medical College, 1893; aged 59; at one time a member of the Medical Association of Georgia; died at his home, November 12.

Newton Elliott Smith, Fayette, Mo.; Washington University, St. Louis, 1903; aged 38; a member of the Missouri State Medical Association; died at his home, October 12, from pneumonia following influenza.

Charles T. Thomas, Lebanon Junction, Ky.; Medical College of Evansville, Ind., 1881; aged 65; a member of the Kentucky State Medical Association; died at his home, October 19, from bronchopneumonia.

Daniel A. Holliday, Fairmont, Ind.; Kentucky School of Medicine, Louisville, 1893; aged 59; formerly a member of the Indiana State Medical Association; died at his home, November 24, from heart disease.

Lieut. Thomas Reed Ferguson ⊕ **M. C., U. S. Army,** Kirkwood, Pa.; Jefferson Medical College, 1906; aged 33; died in the Lancaster, Pa., General Hospital, October 2, from pneumonia following influenza.

Sylvester E. Goss, Wyaconda, Mo.; College of Physicians and Surgeons, Keokuk, Iowa, 1888; aged 56; a member of the Missouri State Medical Association; died at his home, October 4, from heart disease.

Otto C. McDannell, Lowell, Mich.; College of Physicians and Surgeons, Keokuk, Iowa, 1867; aged 74; a member of the Michigan State Medical Society; died at his home, November 20, from influenza.

Austin LaMonte, Carmel, N. Y.; University of Michigan, Ann Arbor, 1861; aged 81; a member of the Medical Society of the State of New York; died at his home, November 9, from arteriosclerosis.

William Lundy Brown, Los Angeles; Bennett Medical College, Chicago, 1875; aged 68; at one time a member of the Medical Society of the State of California; died at his home, November 21.

William C. Jamison, Fairmont, W. Va.; Baltimore University, 1888; aged 67; at one time a member of the West Virginia State Medical Association; died at Weston, W. Va., November 23.

Andrew Orr Hastings, Toronto, Ont.; University of Victoria College, Coburg, Ont.; 1886; L. A. H., Dublin, 1887; aged 63; died at his home, November 21, from a nervous breakdown.

James Farnsworth Rodgers ⊕ Bowling Green, Ky.; Rush Medical College, 1886; aged 61; died in the Deaconess Hospital, Louisville, Ky., August 31, from carcinoma of the stomach.

Isaac P. Primrose, Nelsonville, Ohio; Starling Medical College, Columbus, 1865; aged 86; a member of the Ohio State Medical Association; died at his home, November 23.

Cheever S. Clark, Canton, Ohio; University of Maryland, Baltimore, 1887; aged 60; a member of the Ohio State Medical Association; died at his home, November 22, from arteriosclerosis.

Will L. Allen ⊕ National City, Calif.; King Eclectic Medical College, Des Moines, Iowa, 1889; aged 59; died at his home, November 18, from chronic nephritis.

Andrew Mason Taylor, Caney, Kan. (license, Kansas, 1901); aged 84; a practitioner for sixty years; died at his home, November 25, from arteriosclerosis.

Alfred Dow Long ⊕ San Diego, Calif.; Harvard Medical School, 1907; aged 42; died in the Elwyn Sanitarium, National City, Calif., November 17, from uremia.

Jonas Larson ⊕ Cozad, Neb.; John A. Creighton Medical College, Omaha, 1915; aged 33; died at his home, November 10, from pneumonia following influenza.

Antonio Rubino, Paterson, N. J.; University of Naples, Italy, 1893; aged 51; died in the Barnert Memorial Hospital, Paterson, November 22, from influenza.

William L. L. Foster, Waco, Neb.; Barnes Medical College, St. Louis, 1898; aged 45; died at his home, November 22, from pneumonia following influenza.

DeWitt Clinton Laverty ⊕ Middletown, Pa.; Jefferson Medical College, 1877; aged 60; died in the Harrisburg Hospital, November 14, from appendicitis.

Charles G. Dawley ⊕ Los Angeles; University of Southern California, Los Angeles, 1903; aged 39; died at his home, October 9, from bronchopneumonia.

Aaron A. Nefe, Lookout Mountain, Tenn.; Cincinnati College of Medicine and Surgery, 1869; aged 65; died at his home, November 8, from influenza.

Capt. Pleas Daniel Barnhill ⊕ **M. C., U. S. Army,** Brenham, Texas; University of Texas, Galveston, 1876; aged 52; died October 31, from arteriosclerosis.

Hyman R. Wiener ⊕ Harrisburg, Pa.; University of Maryland, Baltimore, 1912; aged 29; died in the Harrisburg Hospital, October 14, from influenza.

Walter Charles Paine, New Holland, Ill.; Rush Medical College, 1895; aged 52; died at his home, October 13, from pneumonia following influenza.

Linnaeus Jones Hunter, New York City; New York University, New York City, 1889; aged 56; died at his home November 27, from pneumonia.

Lanea Cornelius, Quapaw, Okla.; Hahnemann Medical College, Kansas City, Mo., 1910; aged 33; died at his home, November 7, from pneumonia.

John Meikle Caldwell, Springerville, Ariz.; Detroit College of Medicine and Surgery, 1916; aged 26; died in October at Springerville, from influenza.

Robert Alexander McClelland ⊕ Yorkville, Ill.; Rush Medical College, 1878; aged 64; died at his home, November 29, from cerebral hemorrhage.

John Robert Mason, Lancaster, Tenn.; University of Nashville, Tenn., 1905; aged 36; died in Baltimore, November 20, after a surgical operation.

George W. McDowell, Rockford, Ill.; Hahnemann Medical College, Chicago, 1889; aged 52; died at his home, November 22, from myocarditis.

Henry William Rose, Brooklyn; New York Homeopathic Medical College, New York City, 1876; aged 69; died at his home, November 29.

Hammel House Wright, Little Rock, Ark.; (license, Mississippi, 1910); aged 33; died in Little Rock, October 11, from pneumonia.

B. J. Hardeman, Martin, Tenn. (license, Tennessee, 1889); died at the home of his daughter in Martin, November 18, from influenza.

Stephen L. C. Bredin, East Orange, N. J.; University of Pennsylvania, Philadelphia, 1855; aged 83; died at his home, November 18.

George Lang, Valdosta, Ga.; Savannah, Ga., Medical College, 1861; aged 79; a Confederate veteran; died at his home, November 15.

Maurice C. Jacobs, Kansas City, Mo.; Eclectic Medical Institute, Cincinnati, 1866; aged 80; died at his home, November 16.

Kenneth M. Stell, Cunningham, Texas; Chicago College of Medicine and Surgery, 1911; aged 37; died at his home, October 22.

William Francis Lewis, Anoka, Neb.; Rush Medical College, 1884; aged 57; died at his home, November 22, from pneumonia.

John Henry Blomenkamp, Barada, Neb.; Rush Medical College, 1911; aged 32; died at his home, November 26, from influenza.

Fortunatus James Sconzo, Brooklyn; Long Island College Hospital, Brooklyn, 1917; aged 26; died at his home, October 9.

Mary V. Cosford, Spokane, Wash.; Eclectic Medical Institute, Cincinnati, 1885; aged 62; died at her home, October 28.

Charles Stirling, Oakland, Calif; University of Illinois, Chicago, 1888; aged 63; died at his home, November 28.

W. T. Reagan, McNeil, Ark. (license, Arkansas, 1905); aged 36; died at his home, November 27, from influenza.

Cyrus W. Babcock, Buffalo, N. Y. (license, New York, 1866); aged 81; died at his home, November 7.

James Roy Mains ⊕ Powell, Wyo. (license, Wyoming, 1904); aged 41; died at his home, October 23.

Marriages

Capt. John Harold Carroll, M. C., U. S. Army, New York City, on duty with the American Experitionary Forces in England, to Miss Jean MacGregor, C. A. M. C., on duty with Fifteenth Canadian General Hospital, Taplow, England, in London, September 12.

Asst. Surg. Franklin Myers Goodchild, Lieutenant (junior grade), U. S. Navy, New York City, assigned to duty at the U. S. Naval Hospital, Brooklyn, to Miss Frederika Riesberg of Park-Hill-on-Hudson, N. Y., in New York City, November 16.

Lieut. Lee Wallingford Darrah, R. A. M. C., Brookville, Pa., on duty with the British Experitionary Forces in France, to Miss Margaret Moysey of Knightsbridge, London, England, November 7.

George W. Harpel, Rochester, N. Y., to Miss Grace Tower Tier of Philadelphia, at Llanerch, Pa., November 19.

Homer Burlington Shoup to Miss Cora Harper, both of Sharpsville, Ind., at Logansport, Ind., November 23.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

EMETIN BISMUTH IODID ACCEPTED FOR N. N. R.

Report of the Council on Pharmacy and Chemistry

The Council has voted to accept emetin bismuth iodid for New and Nonofficial Remedies and to include Emetin Bismuth Iodid-Abbott and Bismuth Emetin Iodid-Mulford as accepted brands. It has authorized publication of the following report on emetin bismuth iodid.

W. A. Puckner, Secretary.

Historical: Emetin bismuthous iodid was introduced by A. G. DuMez in 1910. It varies considerably in composition according to its preparation. The sample analyzed by DuMez contained about 29 per cent. of emetin. The compound is insoluble in water and dilute acids, but is decomposed by alkalis. On the basis of these solubility characters, DuMez in 1910 suggested that it should pass the stomach unchanged, and thus have a lesser tendency to produce vomiting and diarrhea; but that it would presumably be decomposed and absorbed in the alkaline intestines.

DuMez did not have any clinical trials made, and his suggestion was neglected, until it was revived by Dale in 1916. Dale took up the subject because of the unsatisfactory results from the hypodermic emetin treatment in chronic cases, and carriers, of amebic dysentery. He assumed that the intestinal ameba at least might be reached more directly by oral administration than by the circulation. He therefore prompted the clinical trial of the DuMez compound, with promising results.

Administration: Dale employed a dosage of 3 grains of emetin bismuth iodid (corresponding to about 1 grain of emetin) daily, for 12 days. This dosage has been followed by subsequent observers. Dale gave the daily quotum at a single dose, during or after a full meal. Some of the others have given it in divided doses, and at different times. Apparently the midday meal is best, since the after-effects then cause the least inconvenience.

Dale also suggested a keratin-coated pill. As the coating of pills with keratin is now generally recognized to be of little value as a means of preventing the disintegration of pills by the gastric juice (Reports Coun. Pharm. & Chem., 1911, p. 58) salol-coated pills or capsules should be tried and also the wax mass proposed by N. S. Davis (The Journal, Oct. 14, 1916, p. 1160) and the procedure of Ballenger and Elder (The Journal, Jan. 17, 1914, p. 197).

Efficiency: All the clinical observers report satisfactory results. The disappearance of amebas from the stools is generally complete and apparently permanent even in chronic cases and carriers, and in patients in whose cases the hypodermic injections had failed. The compilation of Waddell and co-workers (1917) is most comprehensive. It shows about 18 per cent. of failures in carriers. This may be considered an excellent showing. The method in acute cases also is at least equal to the hypodermic administration of emetin hydrochlorid.

Side-Actions: The statements in regard to these vary somewhat, as might be expected. It is clear, however, that the preparation is far from nonirritant and produces much more gastro-intestinal disturbance than does the hypodermic method. Waddell *et al.* report that practically all patients respond either by purging or vomiting or both; the two phenomena being generally of inverse severity.

Low and Dobell state that "some of these [symptoms] recall to one's memory the old ipecacuanha days," although the symptoms are generally not quite so severe. Unfortunately there are no published records of parallel observations on the severity of these symptoms, comparing the plain ipecac treatment, by Simon's method for instance, with the emetin-bismuth compound and with the adsorption preparation ("Alkresta Ipecac").

Waddell *et al.* state that the vomiting starts in about one hour, the diarrhea in three hours. They can be checked only by opiates. Practically no tolerance is acquired. The vomitus generally has the red color of the drug, showing that the keratin coating had dissolved in the stomach. Evidently this confers but little protection. The severity of the nausea and vomiting varies considerably for different patients. This variation is not to be accounted for by variations in the drug, for this was of the same origin in most of the series. Presumably the variable reaction of the stomach may be an important factor in gastric solution and local irritation by the drug. However, it must be remembered that the emesis is largely of central origin (Eggleston and Hatcher, 1915), and therefore could not be avoided by any method that would permit the absorption of the emetin.

Evidently, the side-effects of the drug are still very undesirable, although they do not preclude its use and are less disagreeable than with the old methods of oral administration. In view of the distinct field of usefulness for the oral method from the standpoint of efficiency and convenience, the emetin bismuth iodid preparations have been accepted for New and Nonofficial Remedies.[1] It is desirable that further methods of insuring gastric insolubility be sought. It is also worth while to determine if smaller daily doses may not perhaps be efficient.

Correspondence

GENITAL GONORRHEA IN EARLY CHILDHOOD

To the Editor:—The article by Dr. Haines on "Acquired Genital Syphilis in the Infant" (The Journal, Feb. 9, 1918, p. 370) prompts me to report five cases of gonorrhea in early childhood that came to my notice at my former dispensary clinic in Chiengmai, Siam. I believe that this is a fairly rare condition anywhere. All five cases were in girls ranging from 2 to 7 years of age.

A Chino-Lao girl, aged 2 years, complained of painful micturition. I suspected urinary calculus of the bladder, as this is very common; but examination showed the whole vulva smeared with a thin, creamy pus, a microscopic examination of which disclosed the gonococci in large numbers. I then questioned the father, who with practically no hesitation said that he had gonorrhea and that he had expressed some of the pus from his penis onto his finger and then deliberately rubbed it into the vagina of his daughter. When asked why, he said that if he could only give his infection to a virgin he would be cured at once of his gonorrhea. I understand that such a superstition is common among the negroes of America and may be an explanation as to the source of infection in Dr. Haines' case.

Three little sisters, ranging in age from 4 to 7 years, all seen within ten days of each other, children of a well-to-do Eurasian, presented the same symptom of a purulent discharge from the vagina, and all had gonococci by microscopic examination. The source of infection here was the nurse girl, who performed the act of masturbation with her little charges.

The 5-year-old daughter of a well-to-do Siamese had the same experience as the three sisters. The microscopic findings were positive. This was also a case of congenital syphilis.

In all five cases the treatment consisted in keeping the parts free from pus and applying a 2 per cent. silver nitrate solution once a day, with from 2½ to 5 grains of a hexamethylenamin solution by mouth three times a day. All the patients responded very quickly and were apparently cured in from ten days to a fortnight.

C. W. Mason, M.D., Chieng Rung, Yunnan, China.

INFLUENZA IN HORSE AND MULE

To the Editor:—Physicians are aware of a disease in horses and mules called "influenza." It is [illegible] it is not due to the same cause as influenza of man. However, it may be of interest to know that this disease in horses and mules bears a wonderfully striking resemblance to influenza in man, both in the influenza itself and in its complications.

Influenza in the horse and mule is confined almost exclusively to so-called green horses, namely, those shipped to infected sales stables for the first time. One attack usually produces immunity, but not always. The disease is more or less common during the shipping season every year, but the complications vary greatly from year to year as to their frequency and the virulence of the secondary infection. Such a history is not unlike that of influenza of man.

The cause of influenza in the horse and mule has not been determined, although it is probably a filtrable virus. If the influenza remains uncomplicated, it is of little or no consequence and is referred to as a shipping fever or shipping cold; every few years, however, a general epizootic or local enzootics occur with secondary infections often resulting in the death of many animals. Pneumonia and other respiratory complications are most common, although in some instances intestinal and nervous complications may exist. A bipolar staining organism of the pasteurella group has often been found in the complications.

As a specific disease, the trouble has prevailed throughout this country for a great many years, and many people still recall the serious form it took in 1870-1872, under the general term "epizootic" and the more specific "pink eye." Again, in 1900-1901, a more or less serious outbreak occurred. During the past few years, the complications have varied from year to year. Six years ago this fall and coming winter, some horse dealers located at various sections of the country lost as much as 50 per cent. and more of their shipments. Last fall and winter, losses were frequently quoted from 5 to 25 per cent. of shipments. The Army has likewise been a very heavy loser at all of its concentration and remount depots.

The symptoms of influenza in the horse when uncomplicated are rising temperature to a greater or less degree with a similar increase in the pulse rate and respiration, and loss of appetite to a certain extent, with some indisposition and depression. The mucous membrane of the eye shows more or less watery secretion and yellowish red color (pink eye).

The necropsy findings in uncomplicated influenza are usually limited to a catarrhal condition of the mucous membranes of the respiratory tract and of the eye. When complicated, as previously stated, varying forms and degrees of pneumonia are common, accompanied by frequent pleurisy with effusion. In other cases, the complication is largely that of edema of the lungs, or the edema may be confined to the larynx or extend throughout the whole of the respiratory tract. Again, in some instances, the predominating complication is marked by a very acute inflammation of the intestine, which previously led to a profuse diarrhea. In still other cases, the most marked findings have been an inflammation of the meninges of the brain and spinal cord.

Prophylaxis against the influenza is to be largely effected by sanitary measures in keeping susceptible animals unexposed to the infection, and the disinfection of infected premises. Little has been accomplished in the production of a vaccine or serum preventing the influenza, but apparently good results have been secured in preventing the complications when using vaccines composed of the various organisms found in the different complications.

The treatment of influenza calls for very little other than good hygienic and sanitary measures during the course of the disease, but such measures are only of limited value in the influenza complications. Here again, apparently good results, however, have been attained when the animals are treated early with an immune serum produced by the organisms in the complication. Such serum to be effective, of course, must be administered early in the course of the trouble.

GERMANY'S GUILT FOR INTRODUCING WAR GASES

To the Editor:—In an editorial in The Journal, November 23, you refer to the suggestion that asphyxiating gases be used in warfare as having been rejected by the British government by reason of the inhumanity of the procedure. The actual facts are that at the first Hague convention in 1899, when twenty-six nations were represented, a proposal to prohibit the use of such gases was made and twenty-four nations agreed, the dissenting nations being Great Britain and the United States. In 1907, the matter was again brought up. This was the second general convention. Great Britain gave way and the United States stood alone in refusing to agree to the prohibition.

The chairman of the convention—a Dutch delegate—begged Admiral Mahan—the opponent of the resolution—to sign for the sake of humanity, but he declined. His reasons for this action are given in Hull's book, "The Two Hague Conferences." They are, in my opinion, unanswerable. For further details see James Brown Scott's work on the Hague conferences.

Inasmuch as a Hague rule provides that when belligerents are all signatories to any agreement they should observe this, but if any one takes in an ally that is not signatory the agreement lapses, it follows that the moment the United States entered the war, all agreements in regard to the nonuse of asphyxiating gases would have been canceled.

Henry Leffmann, M.D., Philadelphia.

[Comment.—Germany was the first nation to violate international agreement on the use of asphyxiating gases, employing these in a surprise attack in the battle of Ypres, April 23, 1915, long before the United States entered the war.—Ed.]

REDUCTION OF RESPIRATION FOR INSOMNIA

To the Editor:—I start with the assumption that every insomnia patient has been carefully examined for any pathologic condition, especially for intestinal disorders, and that all medical and surgical conditions have been met.

The suggestions offered herein are for that class of patients that cannot forget their business when they want to sleep and should be asleep, or those who have troubles or worries from which they are unable to travel or take a vacation. My first efforts began about ten years ago, along the popular line of mental gymnastics, in an attempt to control the mental states. Since the dreaming state lies between consciousness and sound sleep, just at the threshold of sleep the idea was to make them dream themselves to sleep. Directions were to avoid reasoning and analysis, to direct any train of thoughts into the absurd and grotesque. Mention is made of this method because it has some value; about 20 per cent. of patients will admit benefit from it alone, and it can be practiced in conjunction with the second experiment. This second method deals with a more primitive physiologic function, which also has a typical threshold phase and is fortunately subject to control of the will, even by those whose minds are fairly racing with themselves.

I am sure that every surgeon, or anybody connected with an operating room, has noticed that patients put to sleep pass through a semiconscious stage in which respirations are slow and shallow; it is often hard to detect them at all until more is given. The same occurs with gas, which does not irritate the respiratory tract. Natural sleep is ushered in in the same manner; the shallow, slow, threshold phase can be studied in this case without the excitement stage. It is through this natural physiologic pathway that we should attempt to lead our subjects and imitate Nature's process.

The subject should be placed in the best possible environment, with good ventilation. He should be quiet and warm, and should be directed to find a comfortable position and stay in it. He should breathe slowly and shallowly, not too slowly at first until the body becomes accustomed or adjusted to being quiet and in the recumbent position. After allowing about ten minutes for this, he should breathe less and less. Different subjects apply the same principle differently; they learn little tricks that suit their own case. Probably the best method is for him to take a fair respiration and hold after exhalation as long as he can with comfort, then slowly take another, exhale and hold again. He should be directed to continue in this manner. The subject may at first feel that he cannot control or diminish his respirations, but a little patience and effort will in a short time (within two weeks) prove that he can.

I have tried this method of respiratory control in about twenty cases during the past year. Results have seemed so good and its applications so simple that I am anxious for others to try it out fairly and report their success.

G. J. Mautz, M.D., Fort Riley, Kan.
First Lieutenant, M. C., U. S. Army.

THE PROPHYLAXIS OF INFLUENZA

To the Editor:—At the end of the first week of the influenza epidemic at Newport (Sept. 15, 1918), while the disease was raging with great severity, 1,000 men were removed from the receiving barracks to the Vanderbilt farm (Camp Admiral Oman), 7 miles out of town. Here they were placed in large pyramidal tents, eight men to each tent.

During the first three days, ninety-three new cases of influenza developed among the men at the camp. September 19, the fourth day at the camp, no new cases developed and the epidemic practically terminated, only an occasional sporadic case of influenza developing thereafter.

The men at the camp mushroomed their tents every sunny day, ate at mess tables placed in the open, and were allowed no liberty during the first five weeks at the camp. It was noticed at the same time that the men in tents at the training station suffered equally with those in the barracks. The explanation of these two apparently diametric experiences lies in the fact that the men in tents at the training station ate in mess halls, where there is more or less group gathering.

The lesson to be learned from the medical experience at Camp Admiral Oman is that epidemic influenza can be checked to a great extent by plenty of fresh air and sun and by the preventing of group gathering and crowding, such as takes place in theaters, churches, etc., in civilian life and in barracks and mess halls in military life.

Charles H. Carroll, M.D., Newport, R. I.
Lieutenant, Junior Grade, U. S. N. R. F.

ADVANTAGES OF A NATIONAL DEPARTMENT OF HEALTH

To the Editor:—I believe The Journal has always favored a national health department or some arrangement by which the national government would have more power to enforce regulations tending to the prevention of disease and handling health problems for the good of the public in general. Conservation of life is more essential than conservation of labor, food, etc. I believe that if you could in some way bring more prominently to the people's mind the fact that during the first year of the war, barring battle fatalities, the death rate in the Army and Navy from disease was only one third as great as that in civil life of men of the same age before the war began, the public would favor such a department. I believe that if the recent epidemic of influenza had been handled by the government in all parts of the United States as it was in the Army and Navy, we would have saved thousands of lives and millions in money to the government and the people. What we would have saved the United States in this one epidemic would have taken care of a special health department for several years to come.

J. H. Wolfe, M.D., Los Angeles.

ORIGIN OF THE USE OF IODIN FOR SKIN STERILIZATION

To the Editor:—In regard to crediting achievements to foreign countries, I wish to record a memorandum:

Generally, perhaps, it is assumed that the use of tincture of iodin for skin disinfection originated with Grossich and was first recorded by him in the *Zentralblatt für Chirurgie,* Oct. 31, 1908, p. 1289. As a matter of fact, I began the use of tincture of iodin for the purpose of skin disinfection in the latter part of the year 1905, in my surgical service, and called attention to it in an article entitled "Some of the Uses of Iodin in Surgical Practice" (The Journal, April 14, 1906, p. 1102). Again, I published an article calling attention to the same method in *American Medicine,* November, 1906.

I reviewed the history of the iodin method of skin sterilization in a paper read before the American Association of Obstetricians and Gynecologists at Louisville, Ky., in September, 1911, and published in the *American Journal of Obstetrics,* 1912, **65,** 6.

J. E. Cannaday, M.D., Charleston, W. Va.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will *not* be *noticed.* Every letter must contain the writer's *name and address,* but these will be omitted, on request.

WEARING UNIFORM AFTER DISCHARGE

To the Editor:—Will you please publish whether or not medical officers can continue to wear their uniforms and insignia after discharge? I would suggest that the Medical Reserve Corps should be open for enlistment to any ex-medical officer who desires to enter, with the privilege of wearing the full regalia with, perhaps, the exception of wearing *the U. S. R. on the coat collar* instead of the U. S. now worn.

F. M. O'Kelley, Sikesman, Mo.

Ex-Captain, M. C., U. S. Army.

Answer.—As noted in The Journal last week in the discussion concerning the demobilization of medical officers, a questionnaire has been or will be sent to medical officers on which they may indicate their desire to remain in the service. Those who are qualified may be admitted to the regular Medical Corps or to the Medical Section of the Officers' Reserve Corps. An earlier ruling of General March stated *that all men honorably discharged from* the service might continue to wear their uniforms for a period of three months. A later ruling states:

> The provision of section 125, national defense act, approved June 3, 1916 (Bull. No. 16, W. D., 1916), which permits any person who has been honorably discharged from the United States Army, Navy, or Marine Corps, Regular or Volunteers, to wear his uniform from the place of discharge to his home, within three months after date of such discharge, is held to apply to reserve officers when transferred from the active to the inactive list. Reserve officers, *therefore, will* be permitted to wear their uniforms from the place of last duty to their homes within three months of the date on which they were transferred to the inactive list.

THE USE OF LIPOVACCINES AGAINST PNEUMONIA

To the Editor:—I read in The Journal, *Nov. 23, 1918, p. 1734,* an item relative to vaccination against pneumonia. Where may the lipovaccine against the pneumococcus be procured?

D. W. Relihan, M.D., Smith Center, Kan.

Answer.—The lipovaccines described are manufactured by the Army Medical Laboratory. So far as we know, they are not yet available commercially, but are *now in the* experimental stage. The following articles on the subject of lipovaccine have appeared in The Journal:

Whitmore, E. R.; Fennel, E. A., and Petersen, W. F.: *Experimental* Investigation of Lipovaccines, *Feb. 16, 1918, p. 427.*

Whitmore, E. R., and Fennel, E. A.: Experimental Investigation of Lipovaccines, March 30, *1918,* p. *902.*

Massachusetts September Examination

Dr. W. P. Bowers, secretary of the Massachusetts Board of Registration in Medicine, reports the oral, practical and written examination held at Boston, Sept. 10-12, 1918. The examination covered 13 subjects and included 70 questions. An average of 75 per cent. was required to pass. Of the 29 candidates examined, 20, including 9 osteopaths, passed, and 9, including 6 osteopaths, failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Chicago Hospital College of Medicine	(1918)	75
Boston University	(1918)	79, 81.8
Harvard University	(1917) 79.3; (1918)	77.1, 77.3, 83.
Tufts College Medical School	(1917) 75; (1918)	75.7, 77.7

FAILED		
University of Maryland	(1916)	73
Middlesex College of Medicine and Surgery	(1918)	57.7
Laval University	(1917)	60

Dr. Bowers also reports that 6 candidates were licensed at the special examinations held for Emergency Influenza Service, from Sept. 27 to and including Oct. 8, 1918. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Johns Hopkins University	(1903)	83.5
Harvard University	(1882) 79.7; (1918)	80.7
University of Michigan Medical School	(1918)	79.5
Eclectic Medical Institute	(1904)	*
Ohio State University College of Hom. Med.	(1918)	81.4

*No grade given.

Colorado October Examination

Dr. David A. Strickler, secretary of the Colorado State Board of Medical Examiners, reports the written examination held at Denver, Oct. 1, 1918. The examination covered 8 subjects and included 80 questions. An average of 75 per cent. was required to pass. Of the 13 candidates who took the physician's and surgeon's examination, 11, including 5 osteopaths, passed, and 2, including 1 osteopath, failed. Two candidates were dismissed on request, and one candidate was refused examination on account of bad moral character. Twenty candidates were licensed on credentials. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Chicago College of Medicine and Surgery	(1918)	90.7
Loyola University	(1917)	82.1
Baltimore Medical College	(1907)	81.8

Book Notices

ANATOMY OF THE HUMAN BODY. By Henry Gray, F.R.S., Lecturer on Anatomy at St. George's Hospital Medical School. Twentieth edition, revised and reedited by Warren H. Lewis, B.S., M.D.; Professor of Physiological Anatomy, Johns Hopkins University. Cloth. Price, $7.50. Pp. 1396, with 1247 illustrations. Philadelphia: Lea & Febiger, 1918.

In the review of so well known a book, nothing more is necessary than to record the changes that have been made. In this edition the special sections on embryology and histology have been distributed among the subjects under which they naturally belong. New matter on physiologic anatomy, laws of bone architecture, and the mechanics and variations of muscles has been added, occupying much of the space formerly devoted to applied anatomy. The sections on ductless glands and the nervous system have been largely rewritten. By means of diagrams and descriptions, the sympathetic nervous system is presented in a more rational manner than heretofore. The central connections of the spinal and cranial nerves are also emphasized. Many new illustrations have been added, especially in the section on the central nervous system.

THE HUMAN SKELETON: AN INTERPRETATION. By Herbert Eugene Walter, Associate Professor of Biology, Brown University. Cloth. Price, $1.75. Pp. 214, with 175 illustrations. New York: The Macmillan Company, 1918.

This is an admirable, succulent and refreshing study of the human skeleton. It is not a study of "dry bones," but is instinct with life in every page. The medical student will find in it constant references to comparative anatomy and the evolution of various bones or their individual parts which will surely arouse his interest and explain the biologic relation of the lower animals to man. The teacher of anatomy will find a freshness of style which helps to make anatomy not only a useful study but an interesting one. The author has also a genial sense of humor, which is as welcome as it is rare in books of this sort. The illustrations are excellent and sometimes new and very informing. They often teach quite as much as the text.

The Growth of Medical Science.—We sometimes speak of the science of medicine; this is euphemism. Often we say medicine is an art founded on science. We like to think of practice as built on the solid foundations of anatomy, physiology and pathology, and these as resting on the bed rock of biology, chemistry and physics. This is camouflage. A better figure is that of a house being gradually moved from ancient piling to granite foundation; from empiricism to experimentalism; from superstition to science. It behooves those who live in the house during the moving operations not to step on the rotten planks in the floor.—E. P. Lyon, *Texas State Journal of Medicine.*

Injury to Employee from Vaccination

(Krout v. J. L. Hudson Co. et al. (Mich.), 166 N. W. R. 848)

The Supreme Court of Michigan sets aside an award of arbitrators that was affirmed by the industrial accident board in proceedings brought for the recovery of compensation for injury alleged to have been sustained by an employee from vaccination. The court says that the claimant was employed as a fitter for the J. L. Hudson Company, respondent, when a general vaccination of the employees of the company was performed by a physician who was an official of the board of health of the city of Detroit, who acted at the request of the board of health. He testified that the request of the board was communicated to the officers of the company, and that those officers through subordinates conveyed the request to the several departments. The claimant, together with several hundred other employees, submitted to the operation. It was her claim that within half an hour after the operation she felt pain in her arm extending upward into her neck, and that this condition continued for four days when she was obliged to discontinue work. Two days later she called a physician who diagnosed her trouble as "acute mastoiditis, lymphatic infection." Five days later he operated on her. The claimant remained in the hospital some two or three weeks and was convalescent for a considerable period thereafter. While the physician who did the vaccinating had himself vaccinated approximately 100,000 persons and testified that he never knew or heard or read of a case of acute mastoiditis being caused by vaccination, it was the opinion of the claimant's family physician that the mastoiditis was the result of a lymphatic infection, the germ of which (streptococcus or pneumococcus) found entrance to the system through the vaccination.

Assuming, then, as found by the industrial accident board, that the mastoiditis was caused by the invasion of the germs through the vaccination wound (though the testimony contained in the record seemed strongly to discredit this theory), there was still an absolute lack of evidence tending to show that the germ secured lodgment in the claimant's arm in the course of her employment. It seems quite clear to the court that the claimant failed to show any connection between her employment in the store of the respondent and the infection following the vaccination. There was nothing in her employment which made her more susceptible to the reception of the germ infection than if she were walking on the street or attending a theater or church. In other words, the risk of infection was such and such only as that to which the general public is exposed. The claimant's injury, if it could be traced to the vaccination, arose, not out of her employment with the respondent, but through the active agency of the Detroit board of health, which for the benefit of the claimant as well as for the benefit of the general public requested her to submit to the operation. The right of the board of health to insist on general vaccination was not involved. The claimant submitted to the operation, though, she asserted, under protest.

No Reason Why Chiropractor Should Be Excepted

(Williamson v. State (Ala.), 78 So. R. 308)

The Court of Appeals of Alabama, in affirming a conviction of defendant Williamson of the offense of treating diseases of human beings by the system of treatment known as "chiropractic," without having a certificate of qualification from the state board of medical examiners, says that, on the admitted facts, the court could well have directed a verdict for the state, and there was nothing in the record of which the defendant could complain. Since the ruling in *Bragg's Case*, 134 Ala. 170, 32 So. 767, the statutes have been amended so as to deny to all persons the privilege of engaging in the calling or profession of treating or offering to treat diseases of human beings by any system of treatment whatsoever who have not obtained a certificate of qualification from the state board of medical examiners. The authority of the board to issue certificates of qualification is not limited to those who desire to enter the profession as homeopathic doctors, but extends to all schools or systems of treatment. The chiropractor is not excluded or discriminated against, and has the same right to apply for a certificate of qualification as does the homeopath or osteopath, and, if granted a certificate of qualification, there is nothing in the law that denies him the right to pursue his method of treatment. The statutory provision concerning persons who propose to engage in the practice of treating disease as a profession and for a livelihood is a police regulation designed to protect the public from the ignorant and incompetent, and it is a matter clearly within legislative competence to prescribe a test by which qualification may be determined, and to confer authority on a designated board to conduct the proper examination through which the test may be applied. This the legislature has done. There being no discrimination against the defendant or his school of practice, there was no reason why he should be excepted from the operation of this police regulation.

Irresistible Impulse as a Defense to Crime

(Hankins v. State (Ark.), 201, S. W. R. 832)

The Supreme Court of Arkansas says, in this homicide case, that in *Bolling v. State*, 54 Ark. 588, 16 S. W. 658, it approved the rules in *McNaghten's Case*, 10 Clark & F. Reps. 199, namely:

> That to establish a defense on the ground of insanity it must be proved by a preponderance of the evidence that at the time of committing the act the accused was under such defect of reason, from disease of the mind, as not to know the nature and quality of the act that he was doing, or, if he did know it, that he did not know that he was doing wrong.
>
> That if the defendant labors under a partial delusion only, and is in other respects sane, he must be considered in the same situation as to responsibility as if the fact with respect to which the delusion exists were real.

But in approving these rules of McNaghten's Case the court did not hold that the doctrine of irresistible impulse caused by disease of the mind would not be a good defense in cases in which the evidence adduced warranted it.

The McNaghten rules were announced in answer to questions propounded by the House of Lords requesting the judges to declare the law of England as to "alleged crimes committed by persons afflicted with insane delusion, in respect of one or more particular subjects or persons." Thus the questions and the answers assumed as a fact that a person might be insane on "one or more particular subjects or persons." Although this idea had prevailed since the days of Sir Matthew Hale, and obtained in England when the McNaghten rules were announced, it now appears that some distinguished authors on medical jurisprudence have come to the conclusion, following the lead of Lords Lyndhurst and Brougham, that, as a scientific fact, it is impossible for a person to be "insane on one or more particular subjects or persons, without being insane on all." Hence they say the rules of McNaghten's Case are wrong and should be wholly ignored. Now it does not follow that the McNaghten rules are unsound even though there be no such thing as partial insanity. The doctrine that the mind is an integer, and, if unsound on one subject from disease, is unsound on all, was announced by Lords Lyndhurst and Brougham in civil cases concerning the capacity to make a will. This court has not approved the doctrine to that extent in civil cases.

The learned authors on medical jurisprudence and the very few courts which have adopted the views that in the trial of criminal cases in which the defense of insanity is set up the entire question of responsibility is to be left to the jury with no other instructions than that, if the act was the product of mental disease, they should acquit, otherwise convict, have been led into this egregious error, as this court takes it, by treating insanity and irresponsibility as if they were convertible terms. By so doing they treat the entire issue in criminal cases, when the defense of insanity is set up, as one of fact, whereas the real issue in such cases is a mixed one of law and fact. It is an issue of fact for the jury to determine whether the accused at the time of the alleged act was afflicted with a mental disease, and an issue of law as to whether the mental disease is such as will render him irresponsible. Therefore the issue of responsibility or irresponsibility in such cases should be submitted to the jury under proper instructions.

If the doctrine of the New Hampshire court that there are no legal rules or tests should be adopted throughout the American Union, it would be nothing short of a national calamity, because that innumerable multitude of mental abberants, commonly called cranks, would then find, over the insanity route, an easy path to immunity from any crimes they might commit. Hence the only safe and practical way of dealing with the subject is found in the legal tests or rules as formulated in McNaghten's Case, as far as they go, and by an addition thereto of the doctrine that irresistible impulse will excuse when caused by disease of the brain.

Impairment of Sight by Wood Alcohol an "Accident"

(Fidelity & Casualty Co. et al. v. Industrial Accident Commission et al. (Calif.), 171 Pac. R. 429)

The Supreme Court of California holds in a case in which a show card sign writer had been for about a year and a half in the habit of using dyes dissolved in wood alcohol and forced through a fine needle by air pressure, though ordinarily he used this appliance only a very small portion of the time, but during the holidays near the end of the period there was a very much greater use of the apparatus, and directly after the holidays, when the pressure of work had somewhat slackened, he used an extraordinary quantity of wood alcohol in cleaning the apparatus and in washing and cleaning his hands, and on January 7 his eyes and optic nerve were exposed to and came into contact with the vapor of wood alcohol in unusual quantity, involving the sudden impairment of his vision, that the injuries so received constituted an "accident" that arose out of and happened in the course of his employment, and were not the result of an occupational disease, within the meaning of the workmen's compensation act, which provided that, without regard to negligence, liability should exist against an employer for any personal injuries sustained by his employees by accident arising out of and in the course of the employment. The court says that many cases might be cited from other states having similar statutes and from England, in which like unforeseen, unexpected and unintended injuries to employees have been classed as "accidents" and held sufficient to justify awards, such as injuries sustained by persons while lifting heavy objects, or through exposure to drafts or chilly air, or icy water in mines, or through the rupture of blood vessels brought on by unusual heat or overexertion, or through the inhalation of poisonous gases, and the like.

Rule as to Privileged Communications Applied to Roentgenologist

(Shaw v. City of Nampa (Idaho), 171 Pac. R. 1132)

The Supreme Court of Idaho applies the rule as to privileged communications to a roentgenologist, in this personal injury case, under the following circumstances, as stated by the court: When the plaintiff was injured, she employed a physician who immediately took her to another town, where he employed a physician to take a roentgen-ray picture of her broken arm. After the picture was taken and developed, the second physician or roentgenologist consulted with the first or plaintiff's regular physician relative to the interpretation of the picture and the treatment to be administered. Counsel for the plaintiff objected to the roentgenologist's testifying as to any facts learned while he was thus employed, which objection the supreme court holds was properly sustained. It appeared from the evidence, the court goes on to say, that the roentgenologist did more than perform mere mechanical work as a photographer, and that he used his knowledge and experience as a physician in interpreting the meaning of the picture, and advised with the plaintiff's regular physician as to what treatment should be given, the plaintiff paying the roentgenologist for his services. The trial court was justified in excluding such evidence as privileged communication, under the Revised Codes of Idaho, Section 5958, Paragraph 4.

4. **Control of Hunger by Drugs.**—The authors report on the effects of various common drugs on the hunger contractions by the use of the balloon method. Atropin sulphate in doses from 1/80 to 1/40 grain hypodermically invariably inhibited contractions and counteracted the effect of pilocarpin and physostigmin in this regard. Pilocarpin, from 1/12 to 1/6 grain, hypodermically, augmented the contractions, accompanied by diminished pulse rate. Physostigmin produces stimulation, particularly by intravenous administration. Coincident with the gastric manifestations, the pulse rate fell as low as 50 beats per minute, and gradually returned to normal with abolition of the gastric effects. Profound inhibition occurs with doses of 1 c.c. of 0.5 per cent. solution of cocain per kilogram. A stimulating effect from camphor is observed only when the drug is administered intramuscularly. In large doses the contractions appear to become more frequent and intense, and the period of activity is prolonged.

As widely employed as strychnin is for its tonic value, there has been no experimental evidence for its supposed gastric effect. With doses of 1/90 to 1/60 grain subcutaneously, stomach tonus was increased, but at the same time the general excitability of the animal was increased so that the increased height of the writing level may have been due to the increased tonus of the abdominal muscles. At the same time, however, there appears to be a definite increase in the hunger contractions themselves. Inhalation of 5-minim pearls of amyl nitrite, often repeated, after short intervals, causes only a temporary inhibition which disappears as soon as the drug is removed from the nostril. Administration of epinephrin causes prompt and marked inhibition of the hunger contractions. Using ampules of ergot intravenously, a temporary inhibition usually followed by lowered tonus was noted, although contractions ensued. Intramuscular injection in one instance gave a tremendous steplike rise, with extremely high tonus level, followed by a short rest, and then another active period. The effect of pituitary preparations was remarkably like that of epinephrin.

5. **Paroxysmal Tachycardia.**—Carter and Wedd report a case of an ectopic rhythm originating in the upper level of the atrium near the pacemaker, conspicuously under the control of subjective inhibitory reflexes, but utterly uninfluenced by vagal stimulation. There was no demonstrable evidence of any accelerator influence or control over the tachycardia.

6. **Concentration of Urea in Human Blood.**—Of 244 hospital patients whose blood had a urea nitrogen concentration of less than 35 mg. per 100 c.c., 206, or 84 per cent., had a concentration of not more than 20 mg. per 100 c.c. Of these 206 cases only eighty-three, or 40 per cent., showed other evidence of renal impairment; but of the remaining thirty-eight cases, twenty-nine, or 77 per cent., showed other renal symptoms. Kast and Wardell conclude that 20 mg. per 100 c.c. may be taken as the upper normal limit of urea nitrogen in the blood of hospital patients, and that for diagnostic purposes the estimation of the blood urea is a satisfactory index of the functioning power of the kidney.

7. **Effect of Ethylhydrocuprein on Experimental Pneumococcus Infections.**—According to Lewis, ethylhydrocuprein can be given to rabbits intravenously and continuously over protracted lengths of time at the rate of 10 mg. per kilogram per hour, without apparent toxic effects. When injected intravenously into rabbits at the rate of 10 mg. per kilogram per hour for seven hours, ethylhydrocuprein produces a slight bactericidal action of the serum. A much higher bactericidal action is produced when it is injected at the rate of 15 mg. per kilogram per hour for seven hours. The effect of a fatal dose of pneumococcus on rabbits is not affected by the continuous intravenous injection of ethylhydrocuprein, in spite of the fact that the animal's blood may be distinctly bactericidal in vitro. The continuous intravenous injection of a soluble bactericidal therapeutic drug has theoretical advantages over the usual single or intermittent dosage. Lewis suggests that the failure of the method with ethylhydrocuprein is probably due to the nature of the drug and not to the method.

8. **Experimental Study of Therapy in Trichinosis.**—Hall and Wigdor carried out a number of experiments in testing the prophylactic and curative value of serum from animals recovered from trichinosis. Their experiments bear out the conclusions of Schwartz to the effect that serum from animals convalescent from trichinosis, when injected into other animals or fed to them mixed with trichinous meat, does not inhibit the customary development of trichinae. On the other hand, theoretic considerations, the clinical observations of Salzer, and the longevity data from their experiments lead Hall and Wigdor to the conclusion that such a serum may be of decided value in combating the toxic features of trichinosis, a conclusion which is in general agreement with Salzer's belief in the value of such a serum.

9. **Metabolism in Hemochromatosis.**—A retention of food iron was found by McClure in the metabolism experiment in a case of hemochromatosis. The hypothesis that there is an abnormal retention of iron in hemochromatosis is held to be consistent with the experimental findings. The basal metabolism and the respiratory quotient, determined by indirect calorimetry, were normal. These findings show that there was no gross disturbance in the intermediary metabolism.

15. **New Treatment for Paralysis Agitans.**—The method of treatment used by Swift consists in muscular movements of a simple nature gone through very slowly, at the rate of about 1 foot to the second, with strong mental concentration on the movement while it is in progress. First come movements of the right foot, then of the left, then of the legs successively, then of the right and left arms in order, then of both arms, and finally of the hands and fingers. The object is not muscular development but development of nervous control over the muscles. The movements should be regular and they should be prescribed definitely. No particular value need be attached to any special set of exercises, because the nervous control is the same in one as in another; however, all the exercises must be done very slowly, at the rate of about 1 foot of movement to the second, if any benefit is to result.

Three cases of definite improvement are mentioned by Swift to show what the method has actually accomplished. One patient complained of a very severe tremor and of great difficulty in getting to sleep at night. Six months of treatment reduced the tremor perceptibly and made it possible for her to get to sleep in fifteen minutes. After only three weeks of treatment a man overcame his tremor to such an extent that he could read his newspaper while holding it in his hands, a thing impossible to him before. A third patient, after three months of treatment, reported that her tremor was reduced by about one third.

17. **Treatment of Infected Wounds Under Battle Conditions.**—This is a report of a "group research" by the Lakeside Unit on the treatment of infected wounds at a base hospital during a battle. In this series, the patients were on the operating table for their first surgical treatment on an average of fifty-eight and one-third hours after injury, the shortest period being twenty-four hours, the longest 150 hours. Every wound that had not progressed to abscess and new tissue formation was treated by complete surgical revision. In large wounds, no attempt was made to excise *en bloc* within the line of uninfected tissue, but the devitalized tissue was dealt with in an opportunist manner. But little skin was excised. Ample exposure was always made, usually by vertical incisions.

After surgically meeting the indication for today, namely, complete revision, the "tomorrow" of the wound was considered, and certain cases were treated by incision of fascia overlying swollen muscles; incision of the skin and superficial fascia, placed where it seemed certain that within the first and second postoperative days swelling and tension would appear; that is, the operation that was anticipated as being necessary day after tomorrow was done now, but owing to these anticipatory or prophylactic incisions, little or no swelling occurred later. When completed, the wound was flat and soft and anticipatory; the obstacles to its biologic defense had been removed. When the wound was surgically completed, it contained many bacteria. It was in the state of a heightened defense clinically. There was active phagocytosis and increased blood supply everywhere; and the infecting bacteria had not gained virulence by selective struggle against antiseptics.

In the period there were admitted, 1,274 patients. Of these, 660 were walkers, and 614 were stretchers. Of the 614 stretcher cases, 194 required no operation, because they were medical cases, or because the wounds were taking care of themselves, and 420 required operation. Of the 420 operative cases, sixty-seven were marked for delayed primary suture; forty-four superficial wounds were immediately sutured. Of the forty-four immediate sutures, all were successful; of the successful cases, there were two fractured humeri and one fractured radius. Of the sixty-seven delayed primary sutures, 91 per cent. healed without requiring removal of any stitches; 6.1 per cent. were partial successes; 2.9 per cent. were failures. Among the total number, ninety-three were compound fractures. There were four, or 0.9 per cent., deaths. There was no case of bacteremia or septicemia. No case was rejected for operation because it was thought that the infection had gone too far. The patients not suitable for delayed suture were quickly ready for evacuation.

The results from this work show that surgical revision of wounds untreated for fifty-eight and one-third hours causes no harm and does much good. It is felt that with further experience a greater percentage of delayed infected wounds, including compound fractures, will be closed both primarily and delayed. The presence or the absence of chemical antiseptics (flavine, Wright's hypertonic pack, alcohol, dichloramin-T, chlorcosane) made no notable impression on the clinical course after operation. Crile says that these results are a tribute to the judgment of the surgeons in the forward area who selected the cases for evacuation without operation and who elected not to pack gauze nor insert drainage tubes into these wounds, but merely dressed them.

19. **Treatment of Infected Hemothorax.**—Impressed by the great improvement in the results obtained by the cleaning out and closing of knee joints which had become infected by wounds, over the results obtained by the old method of drainage, Hutchinson applied this principle to the treatment of infected hemothorax. The method applied is as follows: As soon as the hemothorax is found to be infected, clinically and bacteriologically (nor merely bacteriologically), the patient is taken to the operating room and placed in a partially sitting position on the table. He is then turned a little toward the good side so that the post axillary line is brought well into view. The best anesthetic to use in these cases, Hutchinson says, is nitrous oxid and oxygen. If the patient is in a very bad condition, Hutchinson uses a local anesthetic up to the time of resecting the rib and then a general anesthetic. Chloroform and ether should never be administered. A portion of rib, long enough to allow the hand to be passed through the opening, should be removed and the blood allowed to flow out. The clot is then removed by the hand, all parts of the cavity explored and light adhesions broken down. Then by means of large pieces of gauze on dressing forceps, the remainder of blood and clot is removed. After this, the cavity is washed out with saline and again mopped out and a running suture inserted in such a way as to include the pleura and intercostal muscles. This suture should be left quite loose so that a small quantity of some antiseptic can be poured into the pleural cavity. This antiseptic should be spread all over the walls of the cavity by means of a small piece of gauze on long dressing forceps. As soon as this has been done, the running suture is drawn tight, thus closing the pleural cavity completely. The muscles and skin are then closed and a dry dressing applied.

Forty-eight hours after the operation, the chest should be aspirated, thus removing a quantity of serum and air. Three or four aspirations are necessary during the course of convalescence. The antiseptics Hutchinson used in these cases include eusol solution, a suspension of bipp in liquid paraffin in the following proportions, bipp one-half ounce, liquid petrolatum 6 ounces, flavine solution 1:5,000, and physiologic sodium chlorid solution, the amount left in the chest being 3 ounces. Of twenty-nine cases treated in this manner, sixteen remained closed, thirteen reopened. The bipp gave the best results.

30. **Immunizing Properties of Bacterial Vaccines.**—All vaccines of *B. typhosus* prepared in various ways and including living, autolyzed, chemical and heat-killed and alcohol-killed sensitized sediment, usually produced slight leukocytosis and slight increase of temperature when administered to rabbits by subcutaneous injection in doses according to body weight and comparable to those given to persons; the alcohol-killed sensitized sediment produced these nonspecific reactions in highest degree. Agglutinin and complement fixing antibodies were produced in highest degree by the administration of living and autolyzed vaccines followed in order by the mercurophen-killed, tricresol-killed, heat-killed and alcohol-killed sensitized sediment vaccines. While the agglutination and complement fixation reactions showed in some instances a tendency toward specificity on the part of these antibodies for the particular antigen (vaccine) of *B. typhosus* responsible for their production, the results generally do not indicate definitely the development of specificity to this degree. An antigen of *B. typhosus*, prepared by cultivating the microorganism in plain neutral broth for forty-eight hours and sterilizing the culture with 0.1 per cent. of commercial (40 per cent.) aqueous solution of liquor formaldehydi in a cold dark place over a period of four to five days, proved of particular value in macroscopic agglutination tests. The various vaccines of *B. typhosus* which Perry and Kolmer used as antigens in the complement fixation tests may be arranged as follows in order of antigenic sensitiveness: living and autolyzed; mercurophen-killed; tricresol-killed; alcohol-killed sensitized sediment and heat-killed.

31. **Bactericidal Action of Whole Blood.**—If small numbers of living pneumococci are seeded, by a suitable method, in pigeon's blood before it coagulates, the pneumococci fail to multiply. On the contrary, if pneumococci are seeded in mouse's or rabbit's blood before it coagulates the pneumococci grow with great vigor. The evidence points to the presence in the uncoagulated blood of the pigeon of a bactericidal factor which is absent from the blood of the mouse or rabbit. Fresh defibrinated blood of both immune and susceptible species is an excellent culture medium for the pneumococcus, which shows that the bactericidal factor disappears during the process of coagulation. Pneumococci fail to multiply in the blood of a rabbit which has been suitably inoculated with killed pneumococci, the reaction being specific to type. The blood of a man who has recovered from lobar pneumonia prevents the growth of pneumococci belonging to the type which caused his disease. The globoid bodies of poliomyelitis grow readily in uncoagulated human blood. They fail to grow when seeded in uncoagulated rabbit blood. Many of the nonpathogenic bacteria usually met with as contaminations in bacteriologic work, as, for instance, *B. subtilis*, fail to grow when seeded in uncoagulated blood. The tentative hypothesis advanced by the authors to cover the facts observed by them is that when small numbers of bacteria are seeded in blood before it has had time to coagulate only those bacteria grow and multiply which are pathogenic for the animal from which the blood is taken.

33. **Relation Between Proteolysins and Hemolysins.**—An attempt was made by McNeil and Kahn to find whether proteolytic substances are produced in rabbits on protein injections, if a procedure simulating the production of hemolytic substances in these animals be resorted to. Proteolysis was determined by observing the increase in amino-acid nitrogen after digesting mixtures of the immune serum, the specific protein and complement for a given period. The results gave no evidence of any increase in amino-acids under these conditions, which would indicate that hemolysis and proteolysis are probably two distinct phenomena.

34. **Influencing Complement and Antibody Production.**—The general result of the experiments made by Toyama and Kolmer indicates that while massive doses of arsphenamin and mercuric chlorid tend to suppress antibody production and cause a decrease in hemolytic complement, smaller doses tend to increase the production of antibody (agglutinins)

and augment the complement content after a primary decrease. The authors suggest that it is probable that both drugs administered in the treatment of syphilis owe part of their therapeutic efficacy to their influence on increasing antibody production and complement.

35. **Immunity and Tissue Transplantation.**—A series of experiments was carried out by Fleisher in which the influence of the immune serum on regeneration, leukocytic and connective tissue reaction was studied. Pieces of guinea-pig kidney were transplanted into the subcutaneous tissue of the abdomen of animals, and removed and studied at various periods. At least four pieces of kidney were examined at one, two, four, five, seven, ten, twelve and fourteen days after transplantation; in many cases a very much larger number of pieces was examined. It was noted that in passively immunized animals about homoiotransplants the same reactions occur as in normal animals; about heterotransplants there is possibly a slower clearing of the peripheral portion of the tissue of leukocytes, but otherwise the reactions, even the leukocytic reactions, are like those in normal animals. When tissue is brought into contact with immune serum for a short time before transplantation, there is possibly a slight and brief slowing of connective tissue reaction and regeneration in homoiotransplants. In heterotransplants there is interference with regeneration, which is, however, probably due to the interval elapsing between removal from the living animal and transplantation into the host, and also a slower invasion by leukocytes.

The results of these experiments would suggest that substances in the body fluids of immunized animals have but little influence on the regeneration of transplanted tissue, and that the slowing of leukocytic invasion is in large part due to an action of the serum. The results further suggest that the more marked leukocytic reaction seen about transplants in either immune heterologous animals or immune homologous animals is a direct and independent manifestation of the immunity to the tissue. If these conclusions be correct it appears that, in immunity to tissue transplantation, tissue reactions and especially the reactions of leukocytes play a more important part than do the reactions called forth or produced by the body fluids.

37. **Reading of Hydrogen-Ion Concentration in Bacterial Cultures.**—Bronfenbrenner and Davis use a mixture of equal parts of 0.5 per cent. watery solution of China blue with 1 per cent. solution of rosolic acid in 95 per cent. alcohol. They call it "CR." CR can be added directly to mediums, and permits easy, direct estimation of hydrogen-ion concentration in the culture at all times. Its colors on both sides of neutrality are very brilliant, and therefore a very small amount of indicator is sufficient to give to the medium the desired intensity of color. Bronfenbrenner and Davis keep the indicator in a concentrated solution and add 1 c.c. of this stock solution to each 100 c.c. of medium before sterilization. Heating does not affect this indicator. While the indicator solution keeps sterile on account of alcohol it contains, the heating in sterilization drives it off. Even in the concentration twenty-five times that in which it is present in the medium, CR indicator shows no trace of bactericidal action.

39. **Syngenesioplastic Transplantation.**—The transplantation into early related individuals of the same species is termed syngenesioplastic transplantation by Loeb, a term analogous to those used in the case of transplantation into the same animal, into other individuals of the same species and into different species. He transplanted the thyroid in guinea-pigs from mother to children, from sister and brother to sister or brother, and in one case from child to mother. He followed the fate of the transplanted tissues during different periods after transplantation. After syngenesioplastic transplantation of thyroid in guinea-pigs, the results obtained are intermediate between those obtained after autotransplantation and homoiotransplantation. These findings agree with previous results obtained in the rat and with different organs. After syngenesioplastic transplantation, the thyroid behaves in the majority of cases, for a certain period of time, like an autotransplanted tissue, but in most cases gradually an intense lymphocytic infiltration takes place which secondarily destroys the healthy acini. These experiments are a further proof of the rôle of the lymphocytes in the destruction of tissues under the influence of syngenesiotoxins and homoiotoxins.

In a smaller number of cases of syngenesioplastic transplantations, the fibrous tissue also is increased, the fibroblasts behaving similar to the fibroblasts in cases of homoioplastic transplantation. While in these latter cases the lymphocytic infiltration may be relatively diminished in intensity, the acini are usually not so well preserved as a result of pressure by fibrous tissue. The rapidity with which the transplants attract lymphocytes in various kinds of transplantations is graded, and these gradations correspond to the gradations in the relationships between cell proteins and constituents of the body fluids in donor and host.

40. **Bacteriology of Tuberculous Kidneys.**—The positive proof of the existence or nonexistence of mixed infection in tuberculous processes can be obtained only by a careful bacteriologic examination of such lesions. Inasmuch as a study of pulmonary processes is unsatisfactory, for obvious reasons, Spooner selected the kidney. Eleven tuberculous kidneys were examined. One of these contained a deep sinus, and was secondarily infected. This was excluded from the statistics. In the remaining ten, positive cultures of the tubercle bacillus were obtained in five. There was no growth on any medium in the remaining five, and none on plain and anaerobic mediums in the five positive cases after a period of three months.

In five, or 50 per cent., a pure growth of the tubercle bacillus was obtained. In no case was any organism of secondary infection recovered. In only two cultures was any other growth found. Such growth was always found in a great minority of the cultures examined. Two kidneys, although probably actively tuberculous consisted merely of large pockets of pus and caseous tissue. For this reason the tubercle bacillus could not be recovered. "Pus sacs," referred to in literature for years as evidences of mixed infection, were sterile, without exception.

Tissue implantations yielded positive results in 66 per cent. of the positive cultures; pus in 33 per cent. The growth of the organism in every case was evident in two to five weeks after the original inoculation. In every instance coverglass preparations showed typical acid-fast bacilli.

Cultures from seven urines of patients suffering from tuberculosis of the kidney were examined. In three instances the urine obtained by catheter from the bladder showed growth of organisms other than the tubercle bacillus. In two cases no growth could be obtained. In four cases the urine obtained from the ureter on the infected side showed no growth on ordinary culture mediums after forty-eight hours' incubation. In all of these cases, pus was present in the urine, and tubercle bacilli were demonstrated in smears. Hence Spooner concludes that the urine of tuberculous kidneys, obtained from the ureter, like the tissues of these kidneys, shows no evidence of mixed infection. The bladder urine is often contaminated by other organisms, yet the ureter specimens remain sterile on plain mediums. The clinical diagnosis of renal tuberculosis is suggested by the presence of acid-fast bacilli in the urine. If a pus-containing urine, obtained from the ureter, shows no growth on simple culture mediums after forty-eight hours' incubation, another and very important link is added to the chain of diagnosis of tuberculosis of the kidney.

41. **Multiple Transplantations of the Thyroid.**—Loeb says that in multiple transplantations of the thyroid the individuality differentials of the thyroids of different animals are preserved; they may find expression in a reaction of the host towards the transplant, which is similar in the case of lobes derived from the same animals and differs in the case of lobes derived from different animals. The lymphocytic reaction in the second transplant is not markedly accelerated or intensified over control transplants, even in cases in which the first transplantation had been multiple; this is especially noticeable in experiments in which the second transplant had remained in the host during a period of three or four days. In a considerable number of cases of multiple transplantation, the first transplants were found to a great extent, or completely, destroyed. It is at present uncertain to what extent this is due to unfavorable conditions of a more or less accidental character or to the production of immune substances.

Loeb's results make it very probable that the lymphocytic reaction is, in part, at least, a response of the host to primary homoiotoxins (syngenesiotoxins) and that it is not entirely the result of the development of immune substances. It is probable that the cell constituent which, directly or indirectly, gives rise to the original formation of homoiotoxins (syngenesiotoxins), may also act as antigen and call forth the production of immune substances which, after combination with the antigen, act on the host cells in a way similar to the primary homoiotoxins (syngenesiotoxins).

42. **Increased Susceptibility of Roentgenized Guinea-Pigs to Tubercle Bacillus Inoculation.**—The technic used by Kellert was: 5 milliamperes; time, 10 minutes; spark gap, 7 to 8.5 inches. A Wappler generator and Coolidge tube having a moderately sharp focus were used. The bottom of the box containing the animal was placed at a distance of twelve inches from the center of the target. A thin wood cover closed the box. The animals were injected with tubercle bacilli either intraperitoneally or subcutaneously, and for each radiated animal a nonrayed one was provided as a control. Exposures were made on the day of inoculation or the following day. After exposure the radiated animal and control were kept in the same cage under similar conditions Kellert found that radiated guinea-pigs are rendered more susceptible to contaminating and to secondary infection, and that the method is of no practical value in routine diagnosis and is unreliable unless carefully controlled by the use of the accepted methods which have become standard in laboratory practice.

43. **Properties of Pneumotoxin.**—Concerning the share of pneumotoxin in the pathology of lobar pneumonia, Weiss suggests that prolonged chilling of the body due to exposure initiates the continuous liberation of large quantities of toxin by the action of normal body enzymes on pneumococci normally localized in the lung alveoli and that this accounts for the initial toxemia. The formation of the exudate is considered to be in part due to an increased permeability of the endothelial cells of the lung for various serum albumins, globulins, fibrinogen and enzymes as the result of the injury exerted by the toxin on their cement substance. The toxin is also regarded as a lymphagogue. It hinders the autolysis of the exudate and the favorable action of antipneumococcus-immune bodies and thus aids in the formation of toxic proteoses and peptones. With the production of excess amounts of specific antibodies and of bactericidal and phagocytic substances, the deleterious and autolysis-inhibiting influences of the toxins and proteoses are neutralized. Autolysis of the exudate is now unhindered and the products are nontoxic amino acids. The equilibrium of this system being governed by the laws of mass action, the change from febrile toxemia to the afebrile atoxic state is necessarily an abrupt one—crisis. Hemoptysis and icterus in pneumonia are regarded as partly or entirely the result of the hemolytic activity of pneumotoxin.

Medical Record, New York

72. **A Wassermann Modification.**—Besides the diluents, only three reagents are used by Shaweker, namely, patient's serum, which must be fresh; acetone insoluble antigen, and guinea-pig cell suspension. The patient's serum serves the triple capacity of complement, amboceptor and reagent. Antigen is made after the method of Noguchi and used in strength of one fourth of the anticomplementary unit. When active serum is used, the acetone-insoluble antigen must be used to reduce the chances of false prototrophic fixation. The cells are collected by cardiac puncture of an anesthetized guinea-pig. The blood is citrated and given two or more subsequent washings with normal salt solution. Natural agglutinins have not been observed. The patient's serum is used in doses of 0.1 c.c. to each tube and should be fresh, free from cells, and not hemolyzed. In testing a spinal fluid, 0.1 c.c. of a known negative serum must be used to furnish complement and amboceptor. The titrations required in this modification are to determine the anticomplementary unit of the antigen used and the cell load which can conveniently be handled by the 0.1 c.c. of patient's serum used. The icebox fixation is used for the first step, four hours to over night being the time allowed. One or two shakings of tubes is sufficient.

1 *Purulent Bronchitis Complicating Measles and Rubella. W. M. MacDonald, T. R. Ritchie, J. C. Fox and P. B. White.—p. 481.
2 Differential Diagnosis of Scarlet Fever, Measles and Rubella. J. S. Warrack.—p. 486.
3 *Incubation Period of Influenza. P. MacDonald and J. C. Lyth. —p. 488.

1. **Purulent Bronchitis Complicating Measles and Rubella.** —An epidemic of exanthematous disease (418 cases) complicated by purulent infection of the bronchi attacked several hundred men. In the large majority there was a copious frothy or mucopurulent bronchorrhea, in seventy-five there was a severe purulent bronchitis, and of these twenty-six died. Taking into consideration only the definite cases of septicemic bronchitis the mortality amounted to one third of the men attacked, but, as practically all the cases showed signs of a much more severe bronchial catarrh than ordinarily occurs in measles, and as the sputa in these cases contained the same organisms as in the more severe ones, the authors believe that it is reasonable to regard them all as cases of multiple infection, and, by doing so, to reduce the mortality to about 7 per cent. Bronchitis with purulent expectoration was common to all the cases, but the severe type consisted rather of a septicemia accompanied by various lung lesions which were not constant but ranged from bronchial catarrh to bronchopneumonia, pleurisy, basal congestion, or lobar pneumonia. No one of these types prevailed, but the seriously ill patients who survived long enough passed through all these phases in succession, although patients usually died before definite lobar pneumonia was well established.

The most striking feature of the physical examination in the early stages was the absence of signs suggesting a marked or extensive involvement of the lung tissue in patients who presented all the clinical features of a severe pneumonia. In the mild cases the breath sounds were harsh and were accompanied by some sharp or sonorous rhonchi and by a few medium crepitations at the base of the lungs. In the more severe cases the signs of bronchitis were more marked and passed into those of bronchopneumonia with patches of dulness on the posterior aspect, deficient or, less frequently, bronchovesicular breathing, and usually some pleural friction. Signs of pleural effusion were rare and empyema never supervened. Evidence of consolidation (at one or both bases, more often the right, and occasionally at one apex) was present in most of the fatal cases for a day or two before death, but in some these signs were absent or very slightly marked. Toward the end coarse bubbling râles could be heard all over both lungs.

The use of drugs was confined to symptomatic treatment in the way of combating the great strain placed on the heart, oxygenating the lungs, and so aiding the reduced area of normal lung tissue in its functions, helping the drainage of the pus from the lungs by expectoration, and hindering the growth of pyogenic organisms in the lungs by local applications. For this purpose heart stimulants such as brandy, strychnin, and digitalis, ammonium carbonate, oxygen warmed and alcoholized, stimulant expectorants, and antiseptic inhalations were tried.

Three different vaccines were used; no one of these three included all the organisms which appear to be responsible for the clinical symptoms. A. A mixed stock vaccine, consisting of 1,250 million Pfeiffer's bacillus and 250 million Friedländer's bacillus per cubic centimeter. B. A vaccine consisting of two preparations containing (*a*) *Streptococcus lanceolatus* and (*b*) *Streptococcus pyogenes-longus*. C. A. vaccine consisting of two preparations, containing (*a*) *Staphylococcus aureus* and (*b*) pneumococcus, a streptococcus and a gram-negative bacillus. Vaccine A was given always in doses of 300 million Pfeiffer's and 60 million Friedländer's with an interval of four days before a second dose. There was never any untoward reaction. Vaccine B was given in most cases in doses of 25 million *Streptococcus lanceolatus* and 25 million *Streptococcus pyogenes*, though in a few the dose was increased to 125 million *Streptococcus lanceolatus* and 33 million *Streptococcus pyogenes*. No untoward results were experienced from these doses.

Of 36 patients treated with vaccine, 10 died. Of 25 patients untreated with vaccine, 16 died. Of 20 patients treated with Vaccine A alone, 3 died. Of 6 patients treated with Vaccine B alone, 4 died. Of 7 patients treated with Vaccines A and B, 2 died. The good results of the vaccine were seen in an improved general condition rather than in the rapid subsidence of any special symptoms.

3. **Incubation Period of Influenza.**—Citing their own cases, the authors claim that the incubation period for both was forty-one hours.

7 Small Localized Epidemic of Influenza in Hospital Ward. M. G. Foster and H. A. Cookson.—p. 588.

6. **Pyemia Due to Organisms of B. Coli Group.**—Cases of a pecular pyemia, with special involvement of the kidneys, apparently caused by *B. coli* or one of its congeners, have been observed during the last year in Cairo. It was some time before the puzzling pyrexia with its attendant symptoms was recognized as a specific one. Nine cases in all were diagnosed in life, six others were recognized pathologically postmortem. In all but three of the cases which came to necropsy a dysenteric ulceration of the large intestine, and especially of the rectum, was present in all degrees of superficial necrosis and deep ulceration. Out of the six patients under treatment, three gave no history of a chronic diarrhea or dysentery; the remainder had had many such attacks.

The authors surmise that the organisms originally gained entrance to the blood stream through a breach of the mucosal surface in the lower part of the large intestine. The pyemic attack is usually ushered in by severe frontal headache, anorexia, vomiting, and an acute pain localized to one or both kidney regions. This pain radiates along the inguinal canal and terminates in the penis, or may be localized to the scrotum. Blood is often passed in the urine in the initial stages. There is generally some difficulty in micturition, though there may be at the same time no frequency or alteration in amount of urine. There may be no symptoms of vesical trouble whatsoever. Usually the patient looks extremely ill, and is mentally dull; he sweats profusely. The temperature is invariably high (103-104 F.), the pulse weak and rapid (110 or higher). At the outset there is invariably a severe rigor which lasts about ten minutes. The temperature remains elevated for five days and then takes on an undulating and a remittent character. All the urgent symptoms disappear; after a few days of convalescence the patient is able to resume his duties.

After a further seven to fourteen days the temperature suddenly shoots up and is followed by a rigor and vomiting; the former succession of symptoms is repeated seriatim. These relapses, averaging five days, alternating with apyrexial periods of eight to fourteen days, recur with remarkable regularity. The patient grows weaker and progressively more emaciated. Finally he dies of toxemia, it may be with ascites and a profuse diarrhea with fecal incontinence. At this stage the liver and spleen are definitely enlarged.

In cases which progress favorably under treatment the pyrexial cycles continue but diminish in intensity, and the apyrexial periods become gradually more prolonged, as long as five weeks. Such patients rapidly put on flesh, and after a convalescence of three months, during which there is no elevation of temperature, were discharged from hospital. Among diseases most closely resembling it are malaria, undulant and relapsing fevers. In its early stages dysentery, generalized tuberculosis, phlebotomus fever, or one of the enteric group may be suspected.

10. **Blood Pressure and Psychoneuroses.**—Observation has convinced Bousfield that the blood pressure is not only of some value in the differential diagnosis of the psychoneuroses, but that it is also of considerable importance in their treatment. In a pure neurasthenia, unless complicated by organic disease, the blood pressure is usually subnormal. In a conversion hysteria, it is generally normal; in an anxiety-neurosis, it is more often than not considerably above the normal. Bousfield believes that the headache in the anxiety neurosis is caused very often or exaggerated by the slight raising of the blood pressure. By lowering the blood pressure, and thus relieving one of the most distressful symptoms, improvement of the general condition by psychotherapeutic methods takes place more rapidly.

In instances in which a patient can only be seen for about one hour during the week, Bousfield nearly always gives one one-hundredth grain of nitroglycerin nightly for a week, followed, perhaps, by half that dose during the next week. In neurasthenia, improvement follows raising the blood pressure. In such patients, and this seems of some slight value, courses of treatment were either suggestive or psycho-analytic. An interesting fact elucidated by Bousfield during his investigation was that those who suffered from great sweating were, as a rule, those in whom the blood pressure was not relieved so readily by nitroglycerin.

11. **National Medical Service.**—The various schemes for national medical service proposed by different English medical men are criticized by Brend in an analytical way. He says that the general point which it is sought to make is that, owing to the great variety and conditions from locality to locality, anything in the nature of a centralized uniform medical service is impracticable. It is impossible to conceive of satisfactory results following from a service which lays down the same requirements for a rural district and a crowded industrial area. An essential qualification for success is a wide degree of elasticity in accordance with local circumstances. It is submitted, therefore, that the best prospects of increasing the usefulness of the general practitioner to the community will be afforded by dismissing the idea of a national medical service, and considering instead the idea of local medical services, which shall vary according to the needs and type of each locality.

In order that this scheme might be realized, it would be necessary in every district to establish a local authority on which the practitioners of the district would be represented widely. This need not necessarily be a new authority; it might, for example, be simply a subcommittee of the present sanitary authority, to which practitioners were added. But it should be understood that the doctors were not members of this authority simply for the purpose of protecting their own interests but were to be regarded as actually responsible, along with the rest of the committee, in establishing an adequate medical service in their district. The authorities then have an entirely free hand to survey its needs and provide for them accordingly. In some districts, as already pointed out, the practitioners would probably concur in a whole-time salaried service being formed; in others, it would be realized that the great bulk of the work was already done by private practice and there was no need to interfere with this, but that it was necessary to supplement it in various directions. Again there would be freedom to make the additional provision either by the appointment of a certain number of whole-time men or of part-time men, or by payment of private practitioners by a capitation fee.

Whatever scheme is adopted, the consequent legislative changes will be very extensive; and in a position where any course is fraught with difficulties, and where weighty arguments can be brought forward against any proposal, it is Brend's opinion that the minimum of difficulty and the best prospect of success will be attained by permitting a very high degree of local autonomy in this matter.

The war undoubtedly has raised the status of the doctor. It has now been made clear to all that the medical profession must be regarded as an integral part of the national defense against aggression by foreign foe. Professional men of all types—lawyers, merchants, architects, teachers—have all worthily contributed their share as men; the padre and the doctor alone have been called on to play their parts still in their professional capacities. Nor is this change limited to increased recognition of his importance; the actual value of the doctor as a curer of sickness has been substantially increased. Where formerly it may have been that his weekly medical journals accumulated unopened in his consulting room; now, at the mess, in hospital, or in the field, he has been associated with his colleagues, some perhaps high up in the scale of medical eminence, and he has had opportunities of hearing all forms of treatment discussed and has seen new developments of medicine put into practical application. There must be very few men who have not realized that, purely from the point of view of adding to their medical knowledge, they have benefited substantially by their experience in the army medical corps.

14. **Ergot and the Prostate.**—In two cases of enlargement of the prostate reported by Murphy, one a senile enlargement and the other a traumatic inflammation in a young adult, the administration of ergot apparently reduced the obstruction caused by the enlarged prostates. Murphy urges the more frequent use of ergot in these cases. He gives 1 dram every four hours.

19 Mongolian Blue Spot in Brazil. C. Ferreira.—p. 600.
20 *Pancreatic Infantilism. J. Comby.—p. 602.

18. **The Endocrine Glands and the Bones.**—In this instalment of this general review of the pathology of childhood, Hutinel discusses what is known to date of the synergy of the ductless glands, the pluriglandular syndromes, and the malformation of bones and other tissues under the influence of abnormal endocrine functioning: athrepsia and hypotrophy in young infants, and rachitis, the lymphatic state and anemia in older children. These are all dystrophies. The organization of the cellular elements is sluggish and stops before reaching its normal consummation. The elements persist in the intermediate stage and are neither cartilage nor bone. Rachitis in syphilitics is rachitis the same as in other conditions, but as it affects an already sensitized bone, the damage is greater.

20. **Pancreatic Infantilism.**—Comby compares what Byrom Bramwell and others have written on this subject, with a recent communication by Bullrich. (Summarized in The Journal, Sept. 28, 1918, p. 1098.) Bullrich's case seemed to be a typical example of pancreatic insufficiency, but necropsy disclosed that others of the endocrine glands were involved in the clinical picture far more than the pancreas. Pancreas treatment would have had little chance to benefit the patient in such a case. Comby queries whether there are two different syndromes with the same symptomatology, or whether the same affection might in different cases affect merely the pancreas or invade others of the ductless glands.

28. **Prophylaxis of Influenza.**—Vincent reports favorable experiences with masks, and comments on the relative immunity of infants to influenza. In the discussion that followed, Henrot recalled that he had urged in 1874 the general adoption of a protecting mask he had devised for diphtheria and malaria. It was put on and worn like spectacles. His proposal and device were pooh-poohed at the time, although he cited favorable experiences reported by Tyndal in an epidemic in Lancashire after the wearing of masks had been made compulsory. Henrot and his pupils found the masks useful at certain necropsies, and they have been using them thus for forty-four years.

34. **Treatment of Lupus.**—Balzer reports some typical cases to show the benefit which may be realized by application of silver nitrate, zinc or chromic acid to the lesions of tuberculous lupus, protecting them afterward against secondary infection by an occlusive dressing. This also serves to reduce the virulence of the microbes already in the lesion.

36. **Echinococcus Cysts in Liver Simulating Gallstone Mischief.**—The woman of 50 related that she had expelled some gallstones the year before, and, naturally, the jaundice, pains and obstruction of bile were ascribed to cholelithiasis. The liver fissured during the operation and a purulent fluid escaped, but no gallstones were found. The patient succumbed the same day. The diagnosis had wavered between gallstones and a neoplasm; Gouget had been impressed with the abrupt onset of symptoms and the extreme prostration accompanying the pyretic jaundice by the second week. Evidently a fixation test for echinococcus would have given the clue, but this would not be applied in such a case unless every case of cholelithiasis were systematically subjected to it. The liver and bile passages were honeycombed with pus, and a large echinococcus cyst was found in the upper part of the liver, the farthest removed from the biliary passages. Hydatid fragments were found in the common bile duct, and had evidently been responsible for the colics, but the jaundice was probably the consequence of the parenchymatous hepatitis. Accumulating experience has shown the rarity of direct compression as the cause of the obstruction in such cases.

37. **Sclerous Nephritis with Spirochete Jaundice.**—The evidently recent development of the sclerous nephritis, with other features of the case reported, seem to sustain the assumption that the kidney changes were the direct result of the spirochetosis itself. The reason why such changes have not been observed more often with spirochetosis is probably that the latter does not prove fatal at the time. When the kidney disease is observed a few months later, no one thinks of connecting it with the spirochetosis. In the present case the man succumbed to an intercurrent bowel disease, so the spirochetosis damage was discovered at the moment.

39. **Retention in Acute Diseases.**—Achard and Leblanc have applied various methods of exploration of kidney functioning in acute diseases in the last few years, and tabulate the findings in twenty-three cases, mostly of typhoid and pneumonia. The retention of water, urea and chlorids may be due to an acute complicating infectious nephritis but, as a rule, the urine shows a high urea content, up to 40 per thousand or over, in some cases, and the kidneys seem normally permeable. The excessively high urea content of the blood is due merely to the oliguria, and possibly to the disassimilation of nitrogen; this is rendered probable by the contrast in some cases between the high figure of the azotemia (2.78 and 1.86 in two cases) and the high urea output (15.7 and 23.2 in these two cases). As the crisis passes and convalescence is installed, a phase of excessive activity on the part of the kidneys follows. This seems to be a general phenomenon, but its intensity varies from moment to moment, and it may be brief or may persist a long time. Whenever it occurs, there are always indications of a disturbance in the balance of the fluids of the organism: The organism is in a state of crisis, usually secondary to a state of more or less pronounced retention. During this phase, Ambard's ureosecretory constant may be much modified temporarily. Under Widal's influence, the rôle of the kidneys in retention of salt has been regarded as predominant, but Achard and Leblanc insist that to date no conclusive proof has been offered that the state of retention is due to functional insufficiency of the kidneys—a specific impermeability for sodium chlorid. This assumption is merely an attempt to explain the facts observed, and it often does not conform to them. It is actually paradoxical to admit the coexistence of a secretory disturbance of this kind along with a perfectly normal concentrating power on the part of the kidneys. It is far more probable that certain factors acting in the inmost depths of the tissues play an important part in the metabolism of water. The researches of Mayer and Schaeffer on the lipocytic coefficients of the organs seem to throw new light on the question of the capacity of the organism for hydratation, as they reported in the *Journal de physiologie et de pathologie générales*, May, 1913, and January, 1914.

40. **Spirocheturia and War Nephritis.**—Salomon and Neveu have systematically examined the urine for spirochetes in every case of acute nephritis since August, 1916. They found spirochetes in eleven cases of war nephritis with a tendency to edema, but none could be detected in fourteen otherwise similar cases. The spirochetes resembled those of the icterohemorrhagic type but were a little longer, thinner and with more twists. They were found only on repeated examinations, and did not seem to be pathogenic for guinea-pigs.

41. **Meningitis in the Army.**—Among the twenty-eight cases of meningitis observed between last December and May, 1918, several different strains of meningococci were involved, even in the same focus. The mortality was over 56 per cent. The disease had subsided entirely for six months before last December. Then the cases developed at scattered points, and American soldiers were most numerously affected. Infection with the meningococcus B seems to be particularly virulent, and a polyvalent serum has little effect on it.

45. ***Transfusion of Blood in Treatment of Meningococcemia.***—The young soldier's meningococcemia seemed to develop in a series of cycles of allergy of four or five days' duration each, with chills and high fever, eruption and diarrhea, with a brief interval of relief between the cycles. There was a phase of meningitis at one time but it was transient, and the cyclic course was not modified. Each cycle left the patient more debilitated. Serotherapy brought an anaphylactic shock when given by the vein after failure of intraspinal administration. Vaccine therapy and a fixation abscess failed likewise.

Finally, 50 c.c. of citrated blood from a healthy man were infused and the general condition improved at once. The following three days, 20, 10 and 20 c.c. were transfused and the improvement continued, no meningococci being found in the blood. Suspension for two days was followed by return of fever, and no benefit from transfusion of 40 c.c. of blood the fifth day, but 20 c.c. the seventh day brought great improvement, and it continued under repeated transfusion of 20 c.c. of blood the sixth, eighth, ninth, twentieth and twenty-first days, always in the morning. Two weeks later the patient had gained 11 pounds; the reds increased from 2,140,000 to 3,900,000 under the influence of the transfusions. In less than six weeks from the first one, the man left the hospital completely cured. He might have recovered without the transfusion, but it would have been a much slower process and there might have been complications which he escaped by this means. When the transfusion was done at evening, it displayed no beneficial action, but in the morning it warded off the chills, etc. There was no specific action, as the donor had never had meningococcus infection, but it seemed to prevent the development of the anaphylactic phenomena caused by the presence of the meningococci in the blood. The alexin in the blood always showed an increase after the transfusion.

46. **Syphilitic Nephritis and Gangrene.**—The nephritis developed in the man of 43 one year after the primary chancre which had been given thorough specific treatment. The nephritis required hospital treatment, and the albuminuria was brought down from 12, 16 or 18 gm. to 5 or 6, when suddenly symptoms of aortitis became manifest, both thoracic and abdominal. The abdominal aortitis simulated acute appendicitis at first, but the circulation in the legs became defective, with embolism and patches of dry gangrene compelling amputation of one leg. After this, under arsphenamin treatment the man regained his health and earning capacity. The syphilis in this case must have been of a peculiarly malignant type. On account of the aggravation of the nephritis symptoms under the first injections of mercury, the mercury was suspended as the patient seemed to be doing sufficiently well under dieting and repose. But this proved to be a grave mistake, as otherwise the aortitis might have been warded off. Syphilitic nephritis should be given thorough treatment, regardless of transient exacerbation under it. In another case, the nephritis, with 30 gm. of albumin, was finally cured after a number of dramatic fluctuations, by prolonged mercurial and iodid treatment. In the case reported the final recovery was realized only under large doses of arsenobenzol kept up for eighteen months, regardless of the transient exacerbations immediately after each injection.

49 *Ether Dressings. P. Descomps and A. Richard.—p. 229.
50 Suprarenalitis after Dinitrophenol Poisoning. P. Merklen and Malloizel.—p. 233.
51 *Echinococcus Chyluria. P. Remlinger.—p. 235.
52 Acute Nephritis with Scabies. G. Milian.—p. 237.

49. **Ether Dressing.**—Descomps and Richard say that irrigation of wounds with ether has proved its usefulness to such an extent that it seems destined to survive the war as a simple, convenient and effectual complement to dry asepsis. Especially in rural practice, where infrequent changes of dressings must be the rule, it will have a wide field of usefulness, they think. The fats and certain alkaloids in the wound are dissolved by the ether and are drawn up and out of the wound by the capillary attraction of the dressing, so that they no longer are absorbed by the organism or serve as a culture medium for the microbes. The ether also destroys the red corpuscles in the wounds, which leaves the phagocytes free to conquer the microbes. Its principal action therefore is in promoting the autosterilization of wounds, so that it may be regarded as a dressing which supplements the simple, fundamental dry dressing of the aseptic technic. The inflamed region is covered with two or three layers of gauze and this is moistened with the ether three times a day. Above this is a sheet of impermeable tissue and a thick pad of carded cotton. The whole is fastened with gauze, loose in the center and tight around the edges. The ether is renewed through a rubber tube or tubes left for the purpose under the dressing or by working a tube in each time. They use from 10 to 40 c.c. of fresh ether each time. The patient feels a sensation of cold when the ether reaches the tissues. The outer end of the tube is kinked to retard evaporation. The ether diffuses all through the wound which is a great advantage over hypochlorite solutions, which are distributed only by gravity. The ether dressing being practically a dry dressing is free from the disadvantages of a fluid. But the chief usefulness of the ether is in preparing a wound for primary suture. Nothing else can approach it for this, they say.

51. **Echinococcus Chyluria.**—Remlinger reports the cases of a man and of a woman who eliminated in the urine the membranes and vesicles from an echinococcus cyst above the bladder. No operation was attempted in either case and the general condition has kept fair to date. The chyluria was probably due to compression in both cases. It had existed long before there was anything to suggest echinococcus disease.

57 Microbian Flora of Influenza. Orticoni, Barbie and Leclerc.—p. 508.
58 *Convergence of Eyeballs After Shell Concussion. P. Descomps, J. Euzière and P. Merle.—p. 509.

53. **Syphilitic Peritonitis.**—Letulle insists that syphilis attacks the peritoneum much oftener than is generally recognized. He found a positive Wassermann reaction in seventy-four of 154 cases of cirrhosis of the liver, and treatment as for syphilis cured the peritonitis in many of these. This syphilitic peritonitis is largely responsible for the ascites, and as it is curable, this element in the clinical picture can be eliminated. Every case of cirrhosis with ascites should be suspected of syphilis, even when there is a known history of alcoholism or tuberculosis. It follows logically that every case of cirrhosis of the liver should be given systematic and prolonged antisyphilis treatment. No harm will be done in any event, while great benefit may result in case syphilis has any share in the clinical condition. Letulle urges microscopic study of the peritoneum in syphilitics, and gives seven illustrations of different histologic findings liable to be encountered.

54. **Dead Bone with Fracture.**—Leriche and Policard report the results of research which demonstrate that the white denuded bone in a war wound is actually dead, and as much a foreign body as an engrafted segment of bone. It has the advantage over the latter, however, that it is in intimate anatomic connection with live bone, and the process of repair proceeds smoothly through the haversian canals. If these canals are obstructed—and this is the rule when there has been an infectious process at the spot—normal repair is hampered. The microscope thus confirms the clinical experience that an aseptic evolution of the wound in the soft parts is the best guarantee of correct and rapid healing of the fracture.

55. **Infantile Scurvy.**—Comby reiterates that every infant given a sterilized food, either milk or proprietary foods, for several months, without any fresh or living food, is menaced with scurvy. In the fifty-five cases he has encountered, in over forty-five an erroneous diagnosis had been made and the children had been given sodium salicylate for the assumed rheumatism, or they had been treated with electricity and massage for the supposed acute poliomyelitis, or given mercurial treatment for assumed syphilis, or incisions and trephining had been done for supposed acute osteomyelitis. Some had been put in a plaster cast or trough for coxalgia or Pott's disease. In the last few months he has encountered thirteen new cases, and in 90 per cent. the attending physician had failed to recognize the scurvy. One infant recently had been treated for six weeks for rheumatism and then for acute

poliomyelitis, no one heeding the one-sided diet. Comby ordered the child to be left quiet in its cradle, not bathing nor dressing it, nor moving it abruptly in any way. A teaspoonful of grape juice was given twice a day, and fresh milk, boiled, was given instead of condensed milk. In eight days recovery was complete. The children with scurvy are generally between 6 and 18 months old, and the painful pseudoparalysis of the legs is a prominent symptom.

56. **Spirocheturia in Spirochete Jaundice.**—The pathogenic spirochetes are not found in the urine as a rule until between the fifteenth to the twenty-third day of the disease, and they are not regularly present even then.

58. **Convergence of Eyeballs After Shell Concussion.**—This sign of organic injury from shell concussion occurs during equilibration tests. Descomps and his co-workers report ten cases, and they regard it as an indication of some minute focal brain lesion.

62 *Treatment of Severe Influenza with Convalescents' Serum. E. Liebmann.—p. 1393.
63 *Viscosimetry and the Blood Corpuscles. A. Alder.—p. 1405.

59. **Charcoal in Chronic Intestinal Disease.**—Lenz has been giving animal charcoal systematically in cases of chronic disease of the small intestine and other conditions in which absorption of bacterial and other products was poisoning the system. The charcoal is given as far as possible from the meals, and in the smallest amounts that prove effectual, in order to refrain from interfering with the digestive juices. From one to three heaping teaspoonfuls of the charcoal (from 5 to 10 gm.) are taken on retiring, stirred well into a glass of hot water or chamomile, linden flower or valerian tea. In acute phases, up to 20 gm. can be taken. In acute diarrheic conditions during the war, from 80 to 100 gm. were sometimes taken daily. The prolonged treatment with small doses is kept up for a few weeks after tolerance for a more normal diet has been regained. In cases of chronic putrefaction and fermentation dyspepsia and catarrhal conditions in the small intestine, he keeps up this continuous mild charcoal treatment for years, with occasional suspension. When the charcoal tends to induce constipation, he orders an occasional course of alkaline saline mineral waters, a glass cold or hot on rising. This clears out the charcoal from the digestive tract so that the processes of digestion can proceed unhampered.

He has never witnessed any serious by-effects from this prolonged charcoal treatment. Occasionally the charcoal formed lumps in the stools, and there is of course a possibility of anthracosis. Mönch has also recently reported a case in which four days of charcoal treatment were followed by palpitations, rapid pulse and congestion of the face when any alcohol was taken. Lenz witnessed the subsidence of jaundice and of urobilinuria in two cases of gallbladder disease under the influence of the charcoal. The latter seems to spare the liver by binding the toxins in the bowel so the liver is spared the task of detoxicating them. Lichtwitz has reported brilliant success in treatment of pernicious anemia with charcoal, long continued and supplemented with frequent lavage of the stomach. This treatment is based on the assumption of gastro-intestinal autointoxication as the cause of pernicious anemia. This assumption is sustained further by Seyderhelm's discovery that pernicious anemia in horses is caused by the presence of gastrophilus larvae in the stomach.

62. **Serotherapy of Influenza.**—Liebmann reports from the medical clinic at Zurich, in charge of Eichhorst, twenty-three cases of severe pneumonia in influenza in which systematic treatment was applied with convalescent's serum injected subcutaneously or into a muscle. The clinical verdict is favorable although beneficial action was not apparent in every case. The refractory ones were all far advanced, some with septicemic phenomena, evidently from mixed infection. In the other cases, after injection once or twice of 20 or 30 c.c. of convalescent's serum, the pneumonia, pronounced cyanosis and hemorrhagic sputum rapidly subsided and the threatening general condition promptly improved. Other patients with apparently lighter attacks were much longer in recovering than in those cases. In some instances the fever subsided rapidly although the cyanosis and delirium persisted for some time. Extreme caution is necessary to ensure that the serum to be injected is sterile; in one case streptococci were found in the blood on a second examination when it had been apparently sterile at the first examination. He insists that prudence requires three days' control of the cultures from the blood and overinoculation on agar. The serotherapy seems to have an antitoxic action rather than a bactericidal, as it did not ward off recurrences.

63. **Viscosimetric Determination of Volume of Blood Corpuscles.**—Alder shows how the viscosimeter is able to determine the volume of the blood corpuscles, the average size of the separate cells, and the concentration of the hemoglobin in the red corpuscles. His research has shown a most remarkable tenacity in the hemoglobin content of each cell. A given volume of corpuscles can thus be carrier of only a certain amount of hemoglobin. This physiologic property of each cell to always carry the maximum quota of hemoglobin seems to be constant through all pathologic conditions, and he regards it as extremely important from several points of view. The only way by which the organism is able to expose larger amounts of hemoglobin to oxidation in the lungs, is by increasing the numbers of red corpuscles. Even in pernicious anemia, the high color index is due merely to the fact that the cells are larger than normal. There is no appreciable disturbance in chlorosis, etc., until the hemoglobin content falls below the normal figure. Over 99 per cent. of the bulk of the corpuscles is formed of the reds. He took up the plasma in a pipet after the blood had been treated with herudin, and used the plasma to dilute a similar amount of the same blood. By comparison of the specimens then, the volume and the viscosity could be estimated, a system of parallel coordinates allowing the third quantity to be ascertained from the two known quantities. The findings coincide with those of the refractometer and other tests. The average of extensive researches by the different methods shows that the normal proportional bulk of the blood corpuscles is between 42 and 46 per cent., and the bulk of a single red corpuscle averages 88 cubic microns in normal conditions. The range in disease is wide, from 66 cubic microns in chlorosis to 119 and 165 in pernicious anemia. In hemolytic anemia the corpuscles were within the normal range.

67 Varices of Subcutaneous Abdominal Veins. E. Greggio.—p. 636.

65. **Skull Wounds.**—De Castro reiterates that no matter how apparently insignificant a war wound of the skull, operative measures are imperative without delay. The skull wound should be cleared out acording to the same principles as for any wound elsewhere. Titrated solution of calcium hypochlorite solution has proved extremely effectual for this in his experience. He makes a practice of exploring the wound with the finger, using a Kocher forceps guided by the finger to extract any foreign bodies. If a bullet cannot be readily found, he leaves it for a later intervention.

Pediatria, Naples

October, 1918, **26**, No. 10

68 *Asthma in Children. L. M. Spolverini.—p. 569.
69 *Treatment of Chorea. R. Pastore.—p 577.

68. **Asthma in Children.**—Spolverini is inclined to ascribe the tendency to asthma in children to deficient functioning on the part of the sympathetic system innervating the smaller bronchi. This paresis of these nerves allows the vagus nerve

to have predominant control, so that the outcome is practically vagotony, although in reality the vagus is normal. This assumption is sustained by the favorable action of epinephrin in asthma, as this does not paralyze the vagus but merely stimulates its sympathetic antagonist. In his experience with nineteen cases of recurring asthma in children, from 6 months to 10 years old, he was impressed with the constant lymphatic status in all, as also the extremely irritable condition of the nerve terminals, both in the motor and vegetative innervation, and also the nervousness and uricacidemia noted almost constantly in one or both parents. He was further impressed with the benefit under suprarenal treatment, even outside of the attacks of asthma, and also under treatment with iodin and calcium preparations and mineral waters of the Fiuggi and Montecatini types. These children, more than any others, benefit from a return to nature. During the attacks of asthma, 1.5 gm. calcium bromid proved a valuable adjuvant to epinephrin. He gave both by the mouth, not venturing to give the epinephrin by the vein to children. The loss of normal balance in the endocrine system, which seems to be responsible for this asthma-producing neurosis, might be instructively studied on children, especially the assumed hyperproduction of hormones from the lymphatic glands, and the deficient suprarenal functioning.

69. **Magnesium Sulphate in Treatment of Chorea.**—Pastore reviews the literature on the treatment of chronic chorea by intraspinal injection of magnesium sulphate according to Marinesco's technic. Excellent results have been reported by a few but in Caronia's case there were extremely severe by-effects, the child collapsing at once after the injection, with paralysis of all the muscles and unconsciousness, respiration becoming rare, with pauses, and only the heart beat showing signs of life, the temperature dropping to 35 C. Artificial respiration was kept up systematically for about twenty-four hours, with continuous inhalation of oxygen, and the child recovered. There were no further manifestations of the chorea from immediately after the injection. Pastore here reports four cases in which the magnesium sulphate was given in small repeated doses, thus curing the chorea without danger. She made from five to seven intraspinal injections of from 0.1 to 0.2 gm. of magnesium sulphate in a 25 per cent. solution, to a total of 0.4 or 0.5 gm. The intervals were one or two days at first, and three or seven days toward the last. There was no appreciable reaction, and improvement was pronounced after the third injection in one child; after the sixth or seventh in two others. One child was not completely cured, although notably improved by the treatment. In this girl of 11, the third injection was followed for two days by intense headache, superficial respiration and sluggish pupil reactions, and the choreic movements returned, but improvement was pronounced under two more injections of the sulphate.

70 *Plastic Motor Surgery. A. Pellegrini.—p. 746.
71 Typhoid and Paratyphoid Occurring in the Vaccinated. V. Panto.—p. 749.

70. **Motor Control of Artificial Limbs.**—Pellegrini reports the details of four cases in which he remodeled the amputation stump to permit volitional kinetic control of the prosthesis. He also describes one case in which the amputation was done with a special technic for this purpose. A different method was followed in each case, as is described with illustrations, but all were comparatively simple and easy. His experience to date has been more favorable with the extraterminal loop, but each stump has to be considered separately.

72 *Pituitary Insufficiency. M. Pincherle.—p. 337. Concluded.

September, 1918, **16,** No. 9

73 The Population After the War. D. Pacchioni.—p. 449.
74 Growth and Pathology of Twins. A. Borrino.—p. 474. Concluded in No. 10, p. 521.

72. **Pituitary Insufficiency.**—Pincherle gives seven pages of bibliography, and tabulates 116 cases from the literature in which the effect of pituitary treatment was recorded, as also seventeen reports on experimental lesions of the pituitary body. Comparing all this testimony with his own clinical experience amply confirms the connection between abnormal polyuria and backward physical development and pituitary insufficiency. Corroborating minor signs are the effects of pituitary treatment, the extreme tolerance for carbohydrates, the abnormally small sella turcica, anomalies in ossification, and Cushing's thermoreaction, low blood pressure, asthenia and drowsiness. In some of his cases only some of these minor points were evident, and he classifies them as "masked pituitary syndromes." They are important for research on the endocrine system, but the chief importance of their discovery lies in the possibility of improvement and cure under organotherapy. In one of his patients the arrival of puberty was accompanied by considerable development of fat, and menstruation was seriously irregular while some of the sexual characters were abnormal. Pituitary treatment in his cases reduced the excessive diuresis and polydipsia, but did not seem to modify durably the diabetes insipidus. The children increased in height and weight, but not all the signs of backward physical development subsided. Enough were modified, however, to encourage further experiments in this line with great promise. In all his cases albuminuria could be induced by forced lordosis, which indicated a low resisting power on the part of the kidneys.

Annaes Paulistas de Medicina e Cirurgia, S. Paulo

February, 1918, **9,** No. 2

75 *The Amebas Infesting Man. II. Aragão.—p. 25.

75. **Ameba Parasites.**—Aragão discusses the endamebas and their relation to tropical dysentery. The number of cases of the latter has increased constantly in S. Paulo in the last six years, from four to 543 reported cases. He admits only two species parasite in man, the one causing dysentery, and the harmless *E. coli.* Kittens seem to be the best animals for tests with the parasites. The latter can be introduced into the rectum; the encysted forms can be given by the mouth as they are not affected by the gastric juice. The dysenteric symptoms develop in from eight to thirty days. He discusses the features which differentiate the pathogenic from the harmless endameba, especially the small size of the cysts of the former and the small number of nuclei. From one to four is the rule and only exceptionally up to eight, while the cysts of the *E. coli* are about twice as large and have from eight to eighteen nuclei. Persons can be carriers of the dysentery ameba and cysts without ever having had dysentery. The danger from such carriers is obvious. Drugs do not act directly on the encysted forms of the endameba but they check the multiplication of the parasite into these forms. Epinephrin, which Bayma advocates in treatment of amebic disease, acts mainly by keeping down the production of the encysted forms. None of the drugs that act on the *E. histolytica* seem to have the slightest action on the *E. coli.* When there is mixed infection with both, the latter emerges unscathed from the treatment which destroys the histolytica. The latter will keep alive for twenty hours on ice or in feces in a tube of serum or ascitic fluid. They have been kept at room temperature in cool weather for ninety-six hours.

Differentiation is difficult if they are dead, especially when the specimen contains epithelial cells and dead leukocytes. If not dead, motility can sometimes be restored by placing the specimen in the incubator at 37 C. for half an hour or an hour. He recommends for the stain to dilute the 0.5 c.c. of feces in 2 or 3 c.c. of a 0.1 per cent. solution of gentian violet in physiologic solution to which has been added 0.3 per cent. of acetic acid. This keeps the elements of the specimen unaltered for several days. It only exceptionally occurs that the vegetative and the encysted forms are found together. Usually transformation to the encysted form occurs in all the parasites about the same time.

Archivos Latino-Americanos de Pediatria, Buenos Aires

May-June, 1918, **12,** No. 3

76 *Pulmonary Tuberculosis in the Newly Born. M. A. Ugon.—p. 213.
77 *Scurvy in Breast Fed Infant. J. Bonaba.—p. 218.

78 *Streptococcus Septicemia. I. Luisi.—p. 225.
79 Tuberculous Meningitis after Mumps Meningitis. C. Pelfort.—p. 232.
80 *Spasm of Glottis. J. Giampietro.—p. 237.
81 *Tardy Inherited Syphilis of the Liver. A. Casaubon and S. Satanowsky.—p. 243.
82 *Datura Poisoning. C. S. Cometto.—p. 260.
83 Uncontrollable Vomiting in Infants. L. V. Blanco.—p. 267.
84 *Chronic Bronchopneumonia with Recovery. J. P. Garrahan.—p. 272.

76. **Pulmonary Tuberculosis in the Newly Born.**—The two infants described were born a little prematurely and were suckled by their consumptive mothers. One developed signs of pulmonary tuberculosis in a month after birth; the other, not until the third month. Tuberculin tests elicited a positive reaction the fiftieth and the ninetieth days, the responses previously having been negative. Necropsy confirmed the clinical diagnosis.

77. **Scurvy in Breast Fed Infant.**—Bonaba reviews the few cases on record of scurvy in breast fed infants. In the case he reports from his private practice the child was 7 months old and previously healthy, and the parents were healthy also except that the mother was of a nervous temperament.

78. **Empyema from Streptococcus Septicemia.**—The girl of 4 developed the septicemia from an erysipelatous affection of the external genitals. It seemed to spread and involve almost all the organs, with grave toxic symptoms until bilateral empyema developed. This seemed to act like a fixation abscess, with complete recovery after evacuation of the pus and rinsing the pleura with oxygen.

80. **Spasm of the Glottis.**—After forty-nine paroxysms from spasm of the glottis in the first twenty-four hours and thirty-three the next day, the tendency rapidly subsided under a change of diet. The male infant was 5 months old and for two months had been fed irregularly on cow's milk. The prompt improvement and cure followed directly on regulation and change of the diet.

81. **Tardy Syphilis of the Liver.**—The four cases summarized were in children from 7 to 12 years old. One had been given a course of treatment for assumed tuberculous peritonitis as the liver and abdomen were much enlarged and there were frequent attacks of diarrhea and slight fever. Under mercurial treatment conditions promptly returned to normal, and there has been nothing since to suggest a tuberculous process. In two other cases intense pains in the right hypochondrium or attacks of jaundice were cured by mercurial treatment, but the chronically enlarged and knobby liver and spleen did not show much change in the two girls of 11 and 12. The fourth case was in a boy of 11; besides the chronic enlargement of liver and spleen there was a specific bone lesion in one tibia. The course of tardy syphilis of the liver is insidious and chronic, and when definite lesions are installed, they resist the most energetic mercurial treatment as in the last three of the cases described. There was no ascites in any of the children. The chronic liver disease permits long survival in such cases.

82. **Poisoning from Datura.**—The two children had been playing with the fruit of the *chamico*, said to be the popular name for *Datura stramonium*, which explained the delirium, the hallucination of spiders and snakes, the incontinence, extreme dilation of the pupils, convulsions followed by contracture, exaggerated by the slightest touch, and one of the children had a severe eruption suggesting scarlet fever. Both children collapsed when stood on their feet. The bowels were cleared out by injection of a pituitary extract and purgatives, sedatives were given and stimulants, camphorated oil, etc. There was an interval of twenty hours before medical aid reached the children, and the first suspicion from the clinical picture was that the children had rabies.

84. **Chronic Bronchopneumonia.**—Garrahan's patient was a girl of 8 who developed bronchopneumonia in the course of whooping cough. It persisted extremely grave for five months and then subsided completely, without sequels during the two years since. The child required oxygen daily for more than two months, and later in the acute exacerbations. The recurring pains in the spine were relieved by reclining on a hard bed. The vomiting and anorexia hampered nutrition but on milk, soups and lightly alcoholized fluids some strength was regained, and by the second month purées and cooked fruits were given notwithstanding the fever; eggs and fish were added the third month. The final complete recovery shows that the dyspneic, febrile semicachexia in such cases does not necessarily entail an absolutely unfavorable prognosis.

Boletin de la Asociacion Medica de Puerto Rico, San Juan

September, 1918, **14**, No. 120

85 *Prophylaxis of Transmissible Diseases. E. Font.—p. 247.
86 Intravenous Mercurial Treatment of Syphilis. Cabrera.—p. 255.
87 Perforation in Typhoid. F. H. Rivero.—p. 268.

85. **Prophylaxis of Transmissible Diseases in Porto Rico.**—The regulations in Porto Rico compel notification of contagious diseases, not only of the typical cases with certain diagnosis but also those in which the diagnosis is doubtful or the disease so atypical that there is merely suspicion as to its nature. The Public Health Service appointed a permanent commission for the study and investigation of the soil, environment, etc., of the transmissible diseases of all kinds, including those peculiar to the island. The commission is composed of the chief of the Negociado de Enfermedades Transmisibles and his assistant, a pathologist; the chiefs of the chemistry and bacteriology laboratories of the service; the chief sanitary engineer, and an entomologist. Every facility is afforded practitioners for the bacteriologic, chemical and biologic study of each case, and serums and vaccines are supplied free of charge for the indigent. The commission pays special attention to a written or verbal report on unusual cases, making every effort to conduct research that may add to the reputation of the medical corps of the island. Members of the commission go to make investigations on the spot, and have already made valuable contributions to the study of spirochetosis, filariasis, bilharziasis, pellagra, lepra, etc., on persons in quarantine. These investigations have determined, for example, the hitherto unsuspected presence of tropical frambesia in the island, a disease known to be extremely contagious, but which had previously escaped detection and been classed as the superficial lesions of syphilis. The fact that the treatment for the assumed syphilis cured the frambesia, was accepted as the confirmation of the diagnosis.

Brazil Medico, Rio de Janeiro

Aug. 31, 1918, **32**, No. 35

88 Brazilian Gregarinas, 9. C. F. Pinto.—p. 273.
89 *Paralysis of Muscles of Neck. M. Gesteira.—p. 273.

Sept. 7, 1918, **32**, No. 36

90 *The Diagnosis and Prognosis of Heart Disease. O. Clark.—p. 281.

89. **Paralysis of Muscles of Neck.**—Gesteira reports a case of what he calls Figueira's syndrome, the infant of 20 months being unable to hold her head erect. It sagged forward or backward. Lumbar puncture was negative, the cephaloplegia having developed in the midst of apparent health. In another infant it developed soon after diphtheria. The muscles regained normal tone in a few days in both, as also in Figueira's own cases. He ascribes the cephaloplegia to a sporadic atypical poliomyelitis infection, but other infections may be responsible.

90. **Heart Disease in Children.**—Clark emphasizes that medical inspection of schools over several years confirms that pure mitral regurgitation is never fatal if extremely violent physical exercise is avoided. One girl of 9 had strong fremitus and intense murmur during the whole of the diastole, loudest at the base of the heart. The child felt perfectly well and no pathologic antecedents were known. Two years later there was no further trace of the murmur. Clark relates further the case of a man of 71, who at 18 presented signs of mitral insufficiency, but has had no further symptoms from the myocardium during his long life of hard labor since. Physicians sometimes begin to listen to their own heart sounds, and discover a mitral murmur previously ignored and never causing appreciable disturbance. Other instances are related to prove that isolated mitral insufficiency is harmless, so long as exaggerated athletics are avoided. When it induces symptoms, we can be certain that there is concomitant

pericarditis, myocarditis or mitral stenosis. Among 3,000 children he has examined at Rio, he found eleven with severe heart lesions, congenital in three and consecutive to acute rheumatism in eight. In colder countries the average is said to be 12 per thousand, while in Rio, where rheumatism is rare, the average is only 3 per thousand.

99 **Intraspinal Treatment of General Paralysis.* G. R. Lafora.—p. 192.

98. **Fractures of the Skull.**—This extensive article is accompanied by nearly a hundred illustrations, many of them colored, showing among others the cracks produced by a stone weighing 18,765 gm. dropped from a height of about 5 feet on the skull, the cadavers in different positions. Among the other material studied were the necropsy reports of the last eight years in criminal and accident cases. De Petinto's findings confirm that the direction of the fissures can be estimated where the character of the agent dealing the blow and the point of the skull receiving the blow are known. Also that the character of the agent and the site of the blow can be determined from the character of the fracture fissures. He reviews the literature on the subject, including some of the recent war experiences. The fissures always trend toward the opposite and symmetrical point of the skull, fracturing or going around the bone obstacles in their path. The fractures are always direct, but the base of the skull is so much more fragile than the vault of the skull that when the fissure reaches the base it is liable to do much more damage than resulted from the direct impact. The latter may even be overlooked completely. In a hundred skulls examined he found only two in which the primary injury had been at the base of the skull. The above laws apply only to adult skulls; other conditions prevail in the fetal and child skull, as he explains.

99. **Treatment of General Paralysis.**—Lafora declares that he never witnessed such remarkable and such permanent remissions in general paralysis as in cases he has been treating with intraspinal injections of arsphenaminized serum. The rapid clinical improvement was followed more slowly but surely by improvement in the laboratory findings.

106 *Indication with Contracted Pelvis. D. F. Ramos.—p. 354.

105. **Danger of Purgative in Appendicitis.**—The only death in Aragon's seventy-one laparotomies last year was in a case of appendicitis in which a saline purgative had been given the woman behind the attending physician's back. Peritonitis followed, in spite of the prompt operation.

106. **Indications with Contracted Pelvis.**—Ramos declares that the dietetic, medicinal and operative measures introduced in recent years in management of childbirth represent the greatest progress realized in the medical sciences. We now can count on getting the offspring past the absolute or relative stenosis of the superior strait, while leaving the mother in good condition for further pregnancies. The twenty-eight cases he describes show the variety of the indications and the necessity for individualization.

113 Inaccessible Vesico-vaginal Fistulas. A. Turenne.—p. 568.

107. **Plastic Operation on the Nose.**—The passages had become completely obstructed by cicatricial tissue after the young man had been kicked in the nose by a horse. Alonso bored the passages anew and lined them with skin. The grafts healed in place on one side but proved a failure on the other side, which in time healed. The lumen is less ample on this side and the stenosis displays a tendency to recurrence. But on the skin-lined side, practically normal conditions were restored. The grafts were Thiersch flaps with which a tampon of moist gauze was coated, top and all. The tampon fitted tight into the passage and was unmolested for five or six days. Then the central portion of the gauze tampon was pulled out, and the rest dropped off spontaneously not long after.

110. **Intraspinal Echinococcus Cyst.**—Fournier reports a case of paraplegia in a boy of 12 developing suddenly with no other symptoms except pains in the back for the last two weeks, and a similar attack of pains in the upper dorsal vertebrae for two weeks three years before. The motor disturbances were more an ataxia than paralysis; the spinal fluid seemed to be normal and the Wassermann and tuberculin tests elicited no response, but roentgenoscopy showed a process of rarefaction in the fifth dorsal vertebra and sixth rib, the seat of the pains and of some tenderness. A syphilitic osteitis at this point was assumed, but no benefit was derived from specific treatment, the paraplegia growing constantly worse. A successful operation revealed echinococcus cysts in the muscles close to the fifth and sixth dorsal vertebrae and in the posterior perimeningeal space, in the spinal canal, and also in the subpleural tissue on one side. The process was evidently of two or three years' standing and it had eroded vertebrae and yet had caused no persisting pains or root symptoms while the extreme hypotony of the paraplegia was in marked contrast to the exaggeration of the bone, periosteum and tendon reflexes and the foot clonus.

111. **The Eye Signs in Pregnancy Toxemia.**—Platero regards albuminuric retinitis as such a grave condition that he advises systematic examination of the fundus every twenty-five or thirty days after the sixth month of pregnancy. This is the only means to avoid disagreeable surprises. The albuminuric retinitis is usually accompanied by excessively high blood pressure, and is intimately connected with the autointoxication of pregnancy. The prognosis is always grave from the standpoint of vision, although the life is not in danger as with albuminuric retinitis under other conditions. The ophthalmoscopic examination should be supplemented by the determination of the blood pressure and the ureosecretory constant, Ambard's coefficient. Every pregnant woman with albuminuria, he reiterates, is in the grasp of intoxication, and in imminent peril of eclampsia or grave complications, insufficiency of the liver or kidneys, or retinitis. Treatment should aim at detoxication, lowering of the blood pressure and pro-

motion of diuresis. The pregnancy should be interrupted without further delay if vision does not return to normal under five days of medical treatment. He impresses on all pregnant women who consult him the necessity for certain dietetic restrictions, and declares that this spares the women the dangers of autointoxication. His experience has been conclusive in this line. He reports two cases in which the women spurned his dietetic advice and would not believe that their headaches, edema, and other disturbances were traceable to an improper diet, until vision began to be seriously impaired. He stopped all food but gave plenty of water, and purged, and drew 500 c.c. of blood. The urine showed 20 gm. urea, 2 gm. chlorids and 2 gm. albumin. Spontaneous delivery occurred in six days after the urea had dropped to 11.5 gm. and the albumin to traces and all the symptoms subsided. Conditions were graver in the second case, and a still-born fetus was expelled at term. Both women had borne several children and in both, the blood pressure dropped to normal after the venesection.

112. **The Ureter Peril in Gynecologic Surgery.**—Stajano discusses how to avoid injury of the ureters in gynecologic operations, comparing the normal and the pathologic anatomy of the region and especially the course of the ureters near the iliac vessels, the broad ligament and the crossing of the uterine artery, the para-uterine and the terminal segments. The ureter is at the mercy of any lesion developing in the pelvis, displacing or involving it. It is possible to avoid the ordinary dangers of injuring the ureter, but it is impossible to abolish all danger from this source as no one can foresee all the eventualities that may develop from the polymorphous and capricious lesions liable to become installed in the pelvis. He reports four cases of serious injury of the ureter during operations, cutting or ligating it by mistake.

124 Malaria and Quinin Poisoning. A. Nieuwenhuijse.—p. 866.

115. **Autoperception of Retinal Vessels.**—Wassenaar relates that in watching a revolving disk with segments of black and white there comes a time when the impression is perceived of a red or violet background with streams of green color moving across it. The phenomenon is most pronounced when the disk stands in full sunlight and is then moved suddenly into the shade. The retinal vessels then are perceived as darker twisting lines running towards the blind spot, which is distinctly visible. The absence of large vessels in the fovea region is shown anew by these tests.

116. **Thread Test of Gastric Chemistry.**—Van Leersum reports a case in which Einhorn's thread impregnation test permitted the exact localization of a peptic ulcer. Gastro-enterostomy had been done a year and a half before, but the pylorus had not been shut off. The vomiting and the pains, increased by eating and by exercise, and the occult blood in the stools testified to ulceration, although the marked tendency to hysteria had convinced the attending physician that the whole trouble was a gastric neurosis. The Einhorn thread showed a brownish discoloration for a stretch of 2 cm. low on the thread. Immediately below there was an abrupt change in tint to green, showing the action of bile. The assumption therefore was that the new ulcer was in the region of the gastro-enterostomy opening, which roentgenoscopy showed was no longer permeable. This proved to be the case, and after excision of the fistula region with its ulcer, and closure of the pylorus, clinical recovery followed. In a second case this discoloration of the thread between 45 and 50 cm. from the lips, and the abrupt change to green below located the ulcer in the margin of the gastro-enterostomy opening. This patient had already had two operations for gastric ulcer, and refused to permit a third. The thread can be swallowed more readily if a scrap of cracker or meat is tied in the end. There is no need to use the duodenal bucket when the question is merely to locate the bleeding point. The length of the chest, etc., must be taken into account in estimating the location of the tumor from the thread. Einhorn's figures do not give a wide enough range. Van Leersum warns in conclusion that the ease and simplicity of this test commend it to such a degree that there is danger that physicians will use it exclusively and rely too implicitly on its findings. "L'histoire se repète," he says, "and especially in medicine, and this notwithstanding our dearly bought experience teaching us that we should never rely exclusively on any one test, any more than on the anamnesis alone."

118. **Quinin Poisoning.**—Horst describes a case similar to one reported by Nocht in which administration of quinin brought on symptoms like those of blackwater fever, only that the blood did not pass into the urine but there were multiple subcutaneous hemorrhages and bleeding from the gums. This hemorrhagic diathesis returned and subsided parallel to the therapeutic administration of the quinin on three separate occasions, with an interval of two years.

122. **Obstetrics in Wartime.**—Ausems says that he has always preached the advisability of a milk and vegetable diet for pregnant women. This avoids the danger of eclampsia while the fetus does not grow so large as when much meat is eaten. He does not approve of the Prochownick method of dieting as this weakens the woman, while the size of the fetus is not limited by it and labor is not shortened. But the long prevailing war scarcity of meat, fats and sugar has forced women to the simple milk-vegetable diet he has always advocated, and obstetricians are unanimous in extolling its influence on labor. Delivery is brief, and the fetus a little below the average size, but born in good condition by rapid labor. "The uterine contractions were more vigorous and delivery proceeded more rapidly and easily on this compulsory restricted milk-vegetable diet," he reiterates, "than when the women sat by the fleshpots of Egypt."

125. **Induced Pneumothorax in Treatment of Gangrene of the Lung.**—Tobiesen reports the case of a young man who developed a gangrenous process in the apex of one lung from aspiration of septic material. A large cavity resulted, but under artificial pneumothorax conditions were restored to clinically normal in the course of a few weeks. Under any other treatment months would have been required to accomplish the same result, if it could have been realized by other means. In another case a man of 46 developed a gangrenous focus of unknown cause and it kept constantly spreading by small foci. No benefit was derived from the attempts to induce artificial pneumothorax as adhesions, etc., counteracted these attempts. He reviews the scanty literature on pneumothorax induced for other than tuberculous processes.

126. **Influenza.**—Erlendson reports two cases of influenza in which symptoms of heart block developed the second and the eighth days of influenza, and several weeks elapsed before the earning capacity was regained. In several soldiers pleurisy developed as a complication of the influenza.

Wernøe reports three cases of paraparesis as a complication of what he calls *spansk Syge* in two men of 53 and 57, and a woman of 40. The latter is known to have a tendency to hysteria.

THE VALUE OF MODERN BLOOD CHEMISTRY TO THE CLINICIAN *

ALEXANDER O. GETTLER, Ph.D.
Assistant Professor of Chemistry, University and Bellevue Hospital Medical College; Pathologic Chemist, Bellevue Hospital

AND

A. V. St. GEORGE, M.D.
Pathologist, Bellevue Hospital

NEW YORK

The investigation of the chemistry of the blood during the past decade has brought us somewhat nearer to the elucidation of certain clinical problems. We know considerable of the etiology of diseases and still more of their end-results, their pathology. But as to the chemistry of their development and progress, little is known. Particularly is this true of the so-called endogenous, or, perhaps more correctly, the metabolic diseases. It is in the latter group that the most satisfactory chemical results have been obtained.

Certain metabolic alterations, notably the elimination of the catabolic products, are definitely determinable by laboratory methods; and no matter how divergent may be the views on points such as technic, interpretation of results, and consideration of normal or of physiologic factors varying the normal, the findings are valuable as indicating the nature of the disturbances in the process of the abnormal production or of the elimination of waste products. As to the actual seat of the disturbance in the body, one can but accept the results of blood and urine examinations as a link in the chain of evidence; and especially is this true of the early and the unusual or irregular cases of nephritis, cardiac or vascular disease.

In the chemical laboratory at Bellevue Hospital several thousand blood determinations are made annually, and embrace practically all disease conditions. From July, 1915, to April, 1917, approximately 15,000 analyses were made by one of us (Gettler) or under his direct supervision, and it is on some of these figures that our study, commenced a year ago, is based. We have examined all the charts and clinical records of these patients and, when available, the postmortem findings. Publication of the tables has been withheld because of the large space needed for them. Soon, however, we recognized the futility of attempting to group disease processes according to blood findings, with perhaps the exception of those diseases attended by disturbances in renal function, that is, the excretion of waste products. It might be of value to determine the blood constituents in patients afflicted with such comparatively mild diseases as gastritis, or even more severe conditions, such as the pneumonias, etc.; but as a routine procedure, we do not believe that blood analyses, as now practiced, furnish definite ideas unless the individual has some complicating condition in his excretory apparatus. For example, we have a large number of determinations on pneumonia patients, many of them under 30 years of age. The greater number of these cases show no definite retention, even in the chlorids, though the latter, as was pointed out by Carter, are not uncommonly diminished in the urine. In those cases in which there was retention of the nitrogenous products, there usually was an accompanying renal involvement, brought about by toxic products affecting the kidneys. We can safely assume, therefore, that the complicating nephritic lesion was the prime cause of this retention, and not the pneumonia. In those cases in which there was no note of any accompanying renal or cardiac lesion, perhaps some undetermined complication was present. The same applies to other diseases, not only of the respiratory system, but of other parts. Among these, acute yellow atrophy, exophthalmic goiter, syphilis, intestinal obstruction, pernicious anemia, diabetes with coma, fever, persistent vomiting, acute hemorrhage, esophageal stenosis, toxemias of pregnancy, septicemia and streptococcic meningitis were often found to have a slight rise in nonprotein nitrogen, but not in every case.

From the fact that so many disease conditions show a slight rise, we have attributed the cause to four factors:

1. Retention due to impaired kidneys (permanent nephritis; transient, by toxic substances).
2. Retention due to impaired circulation.
3. Abnormally large production, by the breaking down of body protein.
4. Increased intake of nitrogenous material.

In other words, the possibility of complications involving one or another of the metabolic functions of an organ, even if only of a transitory character, and especially if it involve the cardiorenal system, is always to be borne in mind before arriving at any conclusions on blood findings.

We concluded, therefore, that routine studies are of value only in such cases as nephritis and cardiac disease, and in cases of diabetes, furunculosis, carbuncles and gout; and it is primarily on these conditions that we desire to report, although a few others are perhaps worthy of mention. No attempts were made to study these patients on any of the special forms of diet. The blood was usually taken thirty-six hours

---

* From the Department of Pathology, Bellevue and Allied Hospitals, Dr. Douglas Symmers, director.

after admission to the hospital, and after the patient had been on the restricted hospital diet, which is low in its protein content. The technic employed is the same as is now in general use. The values taken as normal are given in Table 1.

TABLE 1.—VALUES TAKEN AS NORMAL

	Mg. in 100 C.c.
Nonprotein nitrogen	From 25 to 40
Urea nitrogen	From 10 to 18
Creatinin	From 0.1 to 0.8
Uric acid	From 0.5 to 3.0
Sugar	From 60 to 110
Alkali reserve	From 53 to 80%

When the chief excretory organ, the kidney, becomes impaired and fails to eliminate the waste products, it is obvious that the degree of retention of these products may be of value in diagnosis and also in prognosis; and more particularly is this true of early cases, as is shown by numerous examples of the following description:

A patient, aged 50, with negative family and personal history, had lived a normal, quiet life, with no excesses in diet, alcohol, exercise, etc. Examination revealed a slightly accentuated aortic second sound, but was otherwise negative. The systolic blood pressure was 135 and the diastolic 95. The urine was pale, straw colored, with a specific gravity of 1.008, and with occasional hyaline casts, but was otherwise negative; the average amount was 2,000 c.c. a day. The blood findings on restricted diet showed nonprotein nitrogen, urea and creatinin somewhat increased. The functional kidney tests were negative.

It is this type of case that bears watching and care. Whether we wish to ascribe these cardiovascular, nephritic and degenerative processes to one of several etiologies, or, for lack of better knowledge, are willing to accept the view expressed by Bishop, that it is a general "poisoning" of all the cells of the body, we know this much, that the majority of such patients are definitely aided by restriction of their nitrogen metabolism and by calling on the accessory avenues of excretion. Definite improvement is noted by a simple subjective and objective examination, and can be measured in figures by a study of the blood chemistry.

NEPHRITIS

Nephritic cases, which include only primary nephritis, form the largest and most interesting group in our series. It is obviously impossible to list all of our cases, as they run into hundreds. Therefore, we are giving only the range between which our values lie (Table 2).

TABLE 2.—RANGE OF VALUES IN NEPHRITIS, TAKEN FROM 600 DETERMINATIONS

Nonprotein nitrogen	From 40 to 460 mg. in 100 c.c. of blood
Urea nitrogen	From 20 to 375 mg. in 100 c.c. of blood
Creatinin	From 2 to 42 mg. in 100 c.c. of blood
Uric acid	From 3 to 17 mg. in 100 c.c. of blood
Sugar	From 75 to 160 mg. in 100 c.c. of blood
Alkali reserve	From 40 to 75 per cent.

Because of the unsettled renal nomenclature, we have used in our conclusions the old classification of nephritis, that is, acute parenchymatous nephritis, chronic parenchymatous nephritis, and chronic interstitial nephritis.

Conclusions.—1. All the waste nitrogen products, nonprotein nitrogen, urea, creatinin and uric acid, are present in increased amounts in cases of true nephritis, and generally, but not invariably, present in greater concentration in the blood of those cases which are primarily considered as chronic interstitial nephritis (retention nephritis). This finding is in agreement with the results of practically all workers.

2. The degree of retention (when taking into account the functional efficiency of the cardiac muscle) is a direct criterion of the severity of the lesion.

3. We agree with Hopkins and Jonas that the sugar content in the blood is similarly increased in nephritis, and, at least in our cases, more marked in the patients suffering with the chronic parenchymatous form of the disease.

4. The alkali reserve is a valuable index of the degree of acidosis present. In our table, it runs considerably lower in the interstitial type of the disease. We would suggest that particular attention be paid to cases with low alkali reserve, as it becomes an important factor in the early recognition of uremia.

5. While we are not presenting figures, in attempting to correlate the clinical findings with the postmortem picture, we agree with Frothingham that there is no definite lesion of nephritis referable to a certain clinical picture. In other words, all the clinical and laboratory evidence in a nephritic patient may point to a certain form of the disease, but the postmortem examination is often not in agreement with the diagnosis made during life.

CARDIAC CONDITIONS

In our cardiac group we have included only those cases having primarily a true endocarditis or myocarditis, regardless of minor secondary involvements of other organs, and have eliminated all cases in which the question of primary cardiac involvement might be raised. It appears to us that the problem as to whether a person with heart disease has a complicating true nephritis, a nephrosis, or merely a renal congestion cannot be determined by chemical examination of the blood. The action of the heart, which is dependent on at least three important factors, namely, the condition of the heart muscle, the state of the nervous mechanism of the heart, and the peripheral influences under certain conditions, requires further study and more accurate physical methods of measurement before we can hope to establish its mechanical efficiency definitely.

TABLE 3.—RANGE OF VALUES IN CARDIAC CONDITIONS, TAKEN FROM ABOUT 350 DETERMINATIONS

Nonprotein nitrogen	From 35 to 220 mg. in 100 c.c. of blood
Urea nitrogen	From 18 to 180 mg. in 100 c.c. of blood
Creatinin	From 1.5 to 12 mg. in 100 c.c. of blood
Uric acid	From 2.5 to 7 mg. in 100 c.c. of blood
Sugar	From 70 to 135 mg. in 100 c.c. of blood
Alkali reserve	From 48 to 75 per cent.

A glance at the values of cardiacs (Table 3) presents nothing of interest except that in general the nitrogenous waste products in cardiac patients do not tend to accumulate in the blood to as high a degree as they do in nephritics; but this varies within wide limits in individual cases, many nephritics running even lower than cardiacs, and there are not a few cases of simple hypertension or hypertension accompanied by some minor change in the cardiac cycle that show no change in the chemical blood picture. Whether or not this retention is solely because of a poor heart muscle, or whether some slight nephritic change is responsible, is a matter still open to question. Judging from our necropsy experience, the hypothesis first expressed appears to be able to cause this retention.

Lewis,[1] Barcroft[2] and others have indicated the importance of studying the volatile and nonvolatile acid content of the blood, particularly in those cases which, for want of a better term, we may signify as cases of cardiac dyspnea. The subject as yet is too complicated to allow of conclusions, but it is worthy of further study.

GOUT

Our arthritic group contains only cases of gout.

TABLE 4.—RANGE OF VALUES IN ARTHRITIC GROUP (GOUT), TAKEN FROM ABOUT 120 DETERMINATIONS

Nonprotein nitrogen	From	30	to	55	mg. in 100 c.c. of blood
Urea nitrogen	From	15	to	35	mg. in 100 c.c. of blood
Creatinin	From	1	to	2.8	mg. in 100 c.c. of blood
Uric acid	From	1.5	to	8.5	mg. in 100 c.c. of blood
Sugar	From	85	to	140	mg. in 100 c.c. of blood
Alkali reserve	From	50	to	80	per cent.

Conclusions.—1. Our cases of gout as a general rule show some increase in the uric acid content of the blood, though some of the chronic cases were within normal limits from this standpoint.

2. The increase is more marked in the acute type of the disease.

3. Our findings are in agreement with Folin and Denis' statement that the uric acid content of the blood in cases of gout is abnormally high without a corresponding increase in the nonprotein nitrogen products of the blood; but the majority of our cases showed a slight but constant increase in the nonprotein nitrogen and creatinin.

4. We believe, as do McClure and Pratt, that an increase of uric acid in the blood, with the patient on a purin-free diet, may be a symptom, but is not diagnostic, of gout.

DIABETES, FURUNCULOSIS, CARBUNCLES, HYPERTHYROIDISM

An increased sugar content of the blood has invariably been found in the untreated cases of diabetes mellitus even without glycosuria. The onset of this condition can be detected in the blood a long time before sugar appears in the urine. It is now well known that because of the variability shown by many kidneys as to their sugar permeability, it is of greater importance to have a blood sugar determination than a determination of the urinary sugar content. The alkali reserve in these cases is also of inestimable importance in diagnosing the degree of acidosis.

The range of values of sugar in diabetes, taken from 800 determinations, has been from 105 to 1,010 mg. in 100 c.c. of blood; the alkali reserve, from 60 down to as low as 7 per cent. Similarly, there have been isolated reports of slightly increased amounts of sugar in furuncles, carbuncles, etc. In our experience, covering some fifty cases of carbuncles and furunculosis, all of severe grade not presenting the symptoms of diabetes mellitus (that is, polyphagia, polyuria, loss of weight and glycosuria), there invariably has been a hyperglycemia, some only of a slight degree, but nevertheless quite definite. It was surprising to see how rapidly these patients improved when they were placed on a carbohydrate-poor diet, in addition to local surgical treatment.

Cases of hyperthyroidism almost always show an increased sugar content of the blood. We believe, however, that this is of little pathologic significance, except that it indicates that the patient's metabolism is on a higher level than in a normal person, and that his reserve carbohydrate is being burnt up; hence the rapid loss of weight so frequently seen in these individuals.

SURGICAL RENAL LESIONS

While as a rule the functional kidney tests furnish us with clearer data in the so-called surgical kidney (multiple abscesses of the kidney, tuberculosis of the kidney, stone, etc.), it may be advisable, especially in elderly patients, to examine the degree of retention of their waste nitrogen products, for they will furnish, as Squier[3] pointed out, a guide to the operability of the individual.

ECLAMPSIA, PERNICIOUS VOMITING, ACUTE YELLOW ATROPHY OF THE LIVER, ETC.

In eclampsia, pernicious vomiting, acute yellow atrophy of the liver, etc., blood figures are of some value again, as indicative of the severity and progress of the lesion, and the same applies to those cases of poisoning which set up a destructive process in the organs of elimination (kidney and liver), for example, mercuric chlorid or arsenic poisoning. However, it must not be overlooked that in such cases of acute mercurial nephritis, we may have an enormous retention which may suddenly disappear, the patient recovering. While to our knowledge such patients have not been followed over a long period of years so as to determine their subsequent course, they are nevertheless apparently perfectly well several years later.

Blood studies on nervous diseases, such as the dystrophies, muscular atrophies, the psychoses and in cretins, have also been made, but results are not yet ready for publications.

GENERAL CONCLUSIONS AS TO VALUE OF BLOOD CHEMISTRY

So much has been written to date on blood chemistry, divergent views often being presented, that the clinician is at sea as to its clinical value. The question before him is, "What does it all mean?" As a result of some 15,000 determinations, the largest ever reported, we conclude that:

1. Kidney function may be ascertained by the increased values of nonprotein nitrogen, urea nitrogen, creatinin and uric acid; that is, whether a derangement in the elimination of the waste nitrogenous products exists.

2. The severity of this derangement can be ascertained.

3. Prognosis can be determined.

4. Hyperglycemia can be detected with certainty by the increased value of the blood sugar content, even in the very earliest stages of diabetes, when the urine is still free from sugar. It is advisable, therefore, to have a blood sugar determination made, even if no diabetic symptoms are apparent.

5. Acidosis and its degree can be determined by the decreased value of alkali reserve of the blood, as measured by the Van Slyke carbon dioxid apparatus.

6. Diagnosis in general, contrary to the views of several workers, is impossible with the blood picture alone. Only three conditions can be ascertained: First, an extremely high retention of nitrogenous substances means a renal involvement, which may be primary or secondary to cardiac; second, a high persistent

blood sugar means a diabetic condition or a tendency thereto, and third, a low alkali reserve means acidosis. Small increases above normal in the nitrogenous values are not characteristic diagnostically, because we find them in scores of various conditions. As an aid in diagnosis to the entire clinical picture, blood chemistry is, of course, most valuable.

7. By reducing in the food of the patient the precursor of the particular substance found in excessive amounts in the blood, very good results are obtained. Especially interesting is this in cases of carbuncles and allied conditions. Here the blood sugar is abnormally high. By cutting down the carbohydrates in the diet the carbuncles clear up beautifully.

8. The practitioner is often met by cases with indefinite, undiagnosable symptoms, in otherwise healthy persons. A blood analysis reveals to him certain abnormalities which he can partially or wholly correct by corresponding diets, and the patients seem to feel much more comfortable, many of them remaining so indefinitely.

9. The chemistry of the blood is of particular practical importance in the toxemias of pregnancy; especially is this true of threatened eclampsia, in which the blood picture (increased amounts of nonprotein nitrogen bodies) indicates the course of treatment to be followed, so as to clear the organism of those retention products. The blood picture, according to the amount of retention, practically always is a safe guide as to the speed with which the uterus is to be emptied, thereby eliminating the focus of toxic absorption. Very often this can be accomplished even before the onset of convulsions.

10. Finally, it must not be overlooked that abnormally high values for nitrogenous waste products are not always due to kidney deficiency. When the values are only slightly higher than normal, a nonprotein nitrogen of from 50 to 60 mg. in 100 c.c. of blood may be due to an abnormally high destruction of body protein or a deficient circulation. In those cases in which the nonprotein nitrogen is very high, 80 or above, in our estimation, the only cause is kidney involvement.

Our fat and cholesterin experiments are in progress and will be reported at a later date.

Puerperal Sepsis in New York City.—According to the *Monthly Bulletin* in New York City during 1917 there were 141,564 births, of which 94,039, or 66.4 per cent., were reported by physicians, and 47,525, or 33.6 per cent., by midwives. Septicemia as a cause of death following childbirth was reported on 238 certificates, or 0.016 per cent. On investigation it was disclosed that 78 of these deaths occurred from sepsis following full time, normal labor; 33 were from sepsis following full time labor requiring operative procedure of some sort; 127 deaths were due to sepsis following premature labor. A comparison of the work of midwives and physicians shows that the midwives with 33.6 per cent. of the births had 35.89 per cent. of deaths from sepsis, while the physician with 66.4 per cent. of the labors had 59 per cent. of the deaths from sepsis following full time labor, a proportion only slightly higher for the midwives, and low for both when the total number of births is considered. The total number of deaths of full time patients in which some operative procedure was necessary was 33, and of these only 4 occurred in cases in which midwives were in attendance previous to the operation. In labors occurring before full term there were 122 deaths from sepsis, 107 among married women, 17 among unmarried women, 2 in widows and 1 in a divorced person. Of these, 53 were reported by the coroner as "abortion" and 12 as "miscarriage."

SPLANCHNOPTOSIS: ITS CAUSE, PREVENTION AND CURE

WITH SPECIAL REFERENCE TO THE DURET-ROVSING OPERATION

GEORGE NOBLE KREIDER, A.M., M.D.
SPRINGFIELD, ILL.

PROLEGOMENON

In May, 1881,[1] Dr. Glénard of Lyons, France, made the observation that many cases of nervous diseases were accompanied by a prolapsed position of the stomach. He proved this by palpation and percussion, which were advanced by his technic to a degree hitherto unknown. He soon afterward found that the other abdominal structures were prone to prolapse, especially the transverse colon, and the right kidney. From the time of this discovery of Glénard we may very properly date an era in the development of the science of medicine.[2]

The profession of France very early recognized the importance of these observations, and we take a lively pleasure at this time of revision in bringing to light a statement made by Fereal, at a meeting of the Hospital Medical Society, Paris, Dec. 24, 1886. After discussing neurasthenia and enteroptosis, he thus proceeded:

> The studies of Glénard confirm the exactitude of the anatomic-physiologic ground which served for the basis of his studies. As to the application of these principles to pathology we must render homage to the original quality which the author has shown in their supposition. Glénard's language shows that he has profound faith and absolute conviction in the correctness of his views, and this is probably the secret of his therapeutic success.
>
> However we may think, French medical men, especially, should acclaim the new ideas emanating from Glénard, and not wait to give them welcome when they may be returned to us from the other side of the Rhine with a borrowed name.

SIGNIFICANCE OF PTOSIS NOT APPRECIATED

I am inclined to believe that the medical profession has not yet appreciated the importance of ptosis of the abdominal organs, or the success of the treatment of these conditions; and it is my object in this paper to call renewed attention to this subject.

Medical men seem prone to overlook the simple and obvious, and to delight in theorizing and speculating as to the cause of obscure disease. This is particularly true regarding neurasthenia and gastroptosis. Hundreds—yes, thousands—of women have been condemned to a miserable existence as hysterics or neurasthenics, who could be relieved if their abdominal ptosis were considered and relieved by bandages or operation. Rovsing says when the day for revision arrives nearly all the so-called nervous affections of the stomach will be found to be ptosis of the stomach. He makes a sharp distinction, which may not be justified, between cases occurring in the virgin, and in the married woman who has undergone several confinements.

THE SYMPTOMS OF GASTROPTOSIS

These patients, when they come for examination, usually exhibit the following conditions:

1. Emaciation.
2. Constipation, or diarrhea alternately with constipation.
3. Nervousness.

---

[1] Note that the date of Glénard's first publication is 1881, not 1883, as usually given.

[2] Glénard: Semaine méd., 1886.

4. They have pains coming on after being on foot several hours, and relief by lying down or by support of the hands or the bandages. These pains are not relieved by lying on the side.

5. Very often there is pulsation of the abdominal aorta, visible especially when in a standing position.

6. There is usually vomiting.

THE GLÉNARD SYNDROME

The Glénard syndrome has been expanded in the course of the years until it now embraces more or less completely the following:

A. 1. Splanchnoptosis.
   2. Gastroptosis.
   3. Enteroptosis.
   4. Coloptosis.
   5. Floating kidney.
   6. Floating liver.
   7. Floating spleen.
   8. Mobile colon.
   9. Hernias of all kinds.
   10. Descensus diaphragmi.
   11. Descensus cordis.
   12. Varicocele.
   13. Hemorrhoids.
   14. Intestinal adhesions, kinks, etc., causing chronic constipation, intestinal catarrh, ulcers and strictures.
   15. Prolapse of the female genital organs.

B. All nervous and mental disturbances resulting from the foregoing, such as neurasthenia, nervous depression and simulated heart disease.

These subdivisions are intimately related, and all deserve consideration; but our present study must be limited almost entirely to prolapse of the stomach and the large bowel. The possible causes of these conditions will be enumerated; the prevention of them will be considered; and some of the measures, physical and surgical, which have been devised for improving pathologic conditions will be detailed.

SHORT STATEMENT OF TOPICS

Much has developed since Glénard first promulgated his fundamental ideas. The one great instructive factor has been the roentgen ray; and from it we have learned that:

1. Only occasionally the stomach is seated in that portion of the abdominal cavity which old theory and anatomic textbooks provided for it. The same is true of the transverse colon.

2. Both sexes and all ages are prone to have displacement of these organs, but females over 30 are afflicted in proportion to males as 4:1.

3. Improper habits of eating and rushing to active labor after meals are probably conducive to prolapse.

4. The corsets and constricting belts of young girls cause weakness of the abdominal muscles, which fail to support the stomach and bowels.

5. High-heeled shoes and insufficient clothing of women are causing muscle strain and congestion of the abdominal contents.

6. The now fashionable constricting leather belts are working similar results in young men.

7. While it may seem to be true that some people have prolapsed organs without symptoms, it is probably much the same condition of affairs that exists when a loop of a bowel is in a hernial sack outside the natural cavity This is always highly interesting and possibly dangerous.

8. There has been a complete change in our conception of the ordinary forms of colitis, and we now believe that these diseases, formerly considered of nervous origin, are primarily not nervous.

9. Many cases of abdominal prolapse can be cured by proper bandaging, posture and dieting, and no operative procedures should be attempted until these simple means have been tried. Especial warning should be given at this point, else we shall have operating perverts bring disrepute on this operation, as they have on appendectomy, etc.

10. Lane's plan of resecting large portions of bowel is only exceptionally necessary, and probably, when the proper attention is given to the early stages of intestinal disease, it will never be done.

11. Operations attaching the stomach and intestine to the abdominal wall are capable of giving good results, even if there are theoretical objections to their employment. Duret of Lille first performed a gastropexy with excellent results, but, unfortunately, this was not appreciated, and it remained for others to develop this operation, notably Rovsing of Copenhagen. My experience would seem to indicate that the operation is not difficult, and can be carried out in patients desperately emaciated, and that good results are often obtained.

12. Infections of the sinuses, teeth and tonsils are, in a great many cases, the cause of that "weakened condition" so often mentioned by authors. This "weakened condition" is responsible for the loss of tone of the muscles of the abdominal wall. The detection of these infections is best obtained by the roentgenogram.

RESTATEMENT AND AMPLIFICATION OF TOPICS

1. *Position of Stomach and Transverse Colon.*—The stomach and transverse colon seldom lie in ideal position. The revelations of the roentgen ray certainly came as a distinct surprise to the older surgeons who had been taught anatomy on the old lines. The illustrations of the more recent textbooks are misleading in this matter. The revelations of the fluoroscope and the roentgenogram are so uniform that we feel amply justified in the statement of the infrequency of the normal position of these organs.

2. *Sex and Age.*—Both sexes and all ages are affected, according to Albu. It seems that even newborn infants are prone to ptosis of the abdominal organs, and, strangely enough, girls are more prone to this condition than boys (11 per cent. boys and 44 per cent. girls).

Again, the aged are particularly prone to prolapses, owing to the bad habits of youth and middle life, to be detailed later.

Stiller[3] says that the Jewish and Slavic races are more prone to the affection than other races, and that residents of cities suffer more than country people.

3. *Habits of Eating.*—Improper habits of eating and failure to rest after meals conduce to prolapse. Any one who observes the daily life in the business centers of our large cities must be impressed with the rapidity with which food is devoured, washed down, usually, with copious drafts of ice water and topped off with ice cream or indigestible dessert. We cannot wonder that the overloaded stomach refuses to act, and "falls down" on the job. For a number of years, I was consulted by many trolley men and conductors on a large electric line who complained of dyspepsia. I

---

[3] Stiller: Berlin. klin. Wchnschr., 1909, 1905, 1899.

found that these men carried, in their buckets, cold, indigestible foods, which they consumed while attending to their exacting duties. That the stomach rebelled was not remarkable.

A country physician's wife, to save her husband annoyance at mealtimes, answered all his telephone calls. Immediately the meal was finished she hastened to prepare her house for any patient who might appear, causing considerable physical and mental agitation during the mealtime and no rest afterward. The result, as might be expected, was a dilated and ptosed stomach. The complication in this case was an ethmoid sinus disease.

4. *Corseting of Young Girls.*—While there has been a certain amount of improvement in the construction of corsets, yet I believe it remains true that the tendency of these "straight jackets" is to squeeze the waist line and interfere with the proper functioning of the abdominal muscles, and thereby the natural support of the abdominal wall is lost. The weight of clothing, held in place by tight bands and strings at the waist line, often adds to the difficulty.

When a girl who has followed this custom comes to her pregnancy she has little muscular support for the wall; and she often supplies this by additional corsets and bandages. When the pregnancy is terminated, the muscles are permanently stretched and weakened, the abdominal contents drop, the uterus sags, varicose veins develop in the legs, hemorrhoidal veins of the rectum become enlarged, and she may became a neurasthenic invalid. All authors agree in laying an indictment against the corset.

5. *High-Heeled Shoes, High-Cut Skirts, and Insufficient Clothing.*—These are causing strain on the muscles and congestion of the abdominal organs. No argument is necessary to prove this.

6. *Clothing of Young Men.*—Suspenders are no longer fashionable for men. Warm underclothing is no longer fashionable. Thin-soled shoes, and no overshoes to protect the feet from cold and dampness, are the vogue. All these tend to ptosis of the abdominal organs. Should we not sound a note of warning?

7. *Prolapsed Organs Without Symptoms.*—We hear and read a great deal about persons having splanchnoptosis without knowing it. This may be true, but much in the same sense that we occasionally find individuals, even doctors of medicine, running around with loops of bowel in both inguinal canals, or even in the scrotum, doing their ordinary professional work. Our duty in such cases is always to warn of impending trouble, and to endeavor to correct the deformity and relieve the conditions causing it. To keep silence is sure to send the patient to an osteopath or a Christian scientist for relief of obscure pains, supposedly in the spinal column, on the one hand, or in the certainly weakened brain, on the other.

8. *Colitis.*—This is no longer to be considered a disease of nervous origin. In a recent work, Osler speaks of "true mucous colitis as a secretion neurosis of the large intestine, met with, particularly, in nervous and hysterical patients. Sometimes there are attacks of nervous diarrhea."

Niemeyer, in 1911, said:

> It is noticeable that the patient is almost always a nervous, hysterical or hypochondriacal individual. The noticeably frequent association of the disease with hysteria and neurasthenia seems to indicate nervous causes for the exaggerated production of mucus. The course of the disease depends on the character of the food taken, and the other nervous symptoms present. The treatment is local and chiefly for the care of the associated neurasthenia.

We believe that modern developments have shown these statements to be absolutely the reverse of true. We believe that the bowel condition usually caused by ptosis of the organs is the primary condition, and that the nervous and mental symptoms are the result. When the enteroptosis is relieved, the nervous and mental symptoms gradually disappear. In this connection it might be well to introduce the historic case of Sir William Treves, cited by Osler, as a case in which laparotomy was resorted to as a medical measure with alleged perfect results.

In a work published in 1898, Mr., now Sir., Frederick Treves[4] wrote:

> An unmarried lady of 30 consulted me with what she was assured was a stricture of the colon. She had the persistent pain and a very marked tenderness at a spot just above and to the left of the umbilicus, to which I have just referred. The stricture was supposed to be situated at this spot. She had frequent vomiting, which appeared in attacks. The vomited matter was small in amount and usually intensely acid. Her bowels were confined, and she described her motions as containing many strange and wondrous things. An examination of one of these remarkable stools revealed nothing unusual, except much undigested food and much mucus. The patient was thin and pallid. She was too weak to follow any other engrossing pursuit, but she had made a great study of her malady. The abdominal pain had begun ten years previously, and since that time she had had manifold illnesses. She had written out an account of these disorders with much care. They seem all to have been of an acute and exceptional character, and included malignant sore throat, internal abscess, spinal exhaustion, neuralgia, and certain smaller troubles. She had had uterine affections of bewildering complexity. She spoke of her kidneys with precision and of her liver with regret. The former organs were prone to unreasonable congestion, and the latter to an obstinacy which appears to have been little short of intelligent. She had been to many health resorts, and had taken medicine for the ten years concerned. She was certainly feeble, anemic, and intensely neurotic. The abdominal pain was, at times, agonizing; and her friends were driven to desperation by an illness which seemed unending and filled with tortures. The abdomen was flabby and revealed nothing beyond a general ptosis of the adbominal viscera of moderate degree.
>
> The kidneys were both slightly movable. As all medical measures had failed, as the patient was leading the miserable life of a chronic invalid, and as her friends were becoming convinced that "she must have something wrong," I consented to make an abdominal exploration. I found a general prolapse of the viscera of moderate but distinct degree; the stomach was perhaps a little dilated, but beyond this every organ in the abdomen was perfectly normal. The intestine was closely examined from the duodenum to the sigmoid flexure; it was perfectly normal.
>
> The exploration cured the patient of all her abdominal symptoms, even of the vomiting, and of the pain which had troubled her for ten years. I think it possible that the ptosis of the mass of intestines may have hindered the passage of food from the stomach in a trifling degree.
>
> This case, therefore, was one of uncomplicated visceroptosis with nervous phenomena in a very neurotic patient. Although the patient had never worn a belt, she was always worse when she moved about, and was only comfortable when in bed. A belt was worn after the operation.

Treves repeatedly refers to the mental effect of the operation. I look on this case as a well marked splanchnoptosis, and its cure not due to the operation or mental effect at all, but to the rest in bed and appropriate bandaging afterward.

---

[4] Treves, in Allbutt: System of Medicine. 1898. 3.

9. *Rest in Bed, Forced Feeding, Posture, Exercise and Proper Bandaging.*—These will relieve nearly all such cases. Usually, the first treatment required for splanchnoptosis is six weeks' rest in bed. The foot of the bed should be raised 12 inches, more or less, depending on the case. A trained nurse should be in attendance to give proper baths and massage. Since these patients are inclined to melancholy, a cheerful, hopeful nurse is essential. Much of the emaciation is due to fear of eating perfectly harmless foods, and they must be urged to eat, even if it causes gastralgia. The stomach has been lazy and must be forced to work. At least five meals a day must be taken. It is usually not desirable to give purgatives. A sun parlor or porch should be used if available, but the patient should be isolated from inquisitive friends or strangers. Complete mental and physical rest is necessary.

After a certain time the supporting bandage should be applied and the patient put on foot. The bandage known as the Comfort U, made for me by E. J. Fayart of Springfield, Ill., is an improved form of the supporter devised by Dr. Gallant of New York. It has certain advantages, which need not be minutely detailed. Suffice it to say that it usually supplies the required support. To this must be added rest in a reclining position for half an hour after each meal, with clothing and bandage loosened, and the foot of the couch or bed elevated. In due time light gymnastics, directed especially to improving the tone of the abdominal muscles and diaphragm, may be taken. We advise shoulders on the floor and hips on a couch, hanging by the knees on a horizontal bar, golf playing, croquet, tennis, etc. Automobile riding is usually painful and should not be permitted until the cure is perfected.

10. *Infrequent Necessity of Lane's Operation.*—Some fifteen years ago Metschnikoff pronounced the colon a useless portion of the intestinal tract. The truth of this statement has not been proved. Following this came the remarkable proposition of Arbuthnot Lane, to excise the greater part of the large bowel for all sorts of ailments. Fortunately, the profession did not hastily accept this dictum. It seems apparent now that it was too broad and sweeping. A few, but not many, patients should be subjected to the Lane operation. Careful attention to the early stages of splanchnoptosis will reduce these cases to the vanishing point.

11. *Gastropexy, First Advocated by Duret of Lille, and Promoted by Rovsing of Copenhagen.*—This operation offers in many cases a hope of relief. Having exhausted all other means of relief, and having proved by repeated studies with the bismuth meal and the roentgenograph that the ptosis exists, it is our duty to give the patient the benefit of the Duret-Rovsing operation.

Duret did a gastropexy in 1894. He reported his case to the Academy of Medicine, Paris, Oct. 2, 1894.

> The patient was a woman of 51, who was afflicted with enteroptosis, together with dilatation and dropping of the stomach to the subumbilical region. All medical treatment having failed, a gastropexy was decided on. An exploration was made for a curable pyloric lesion, and, this being absent, the stomach itself was brought up and its anterior surface fixed to the abdominal wall. The incision was made through the skin and muscle from the ensiform process to the umbilicus. The peritoneum was only opened at the lower angle of the wound, and then fixed at the lesser curvature of the stomach to the untouched peritoneal surface, high up, with a single thread which led alternately in and out through the serosa covering the stomach and the parietal peritoneum. As a result of this simple procedure the stomach and intestinal functions were regulated, and the patient increased notably in weight. The stomach-splashing disappeared below the umbilicus, which proved that the fixation was complete. No roentgenoscopy was available at this date. Some neurasthenic symptoms remained for a time, but later entirely disappeared.

This observation showed that old cases of stomach prolapse could be greatly benefited by a simple operation, and the majority of the distressing symptoms would disappear. At a later session of the Academy (March 19, 1895), Professor Le Dentu reviewed the paper. Le Dentu expressed the opinion that fixation of a hollow organ, like the stomach or intestine, would have no influence on the symptoms, immediate or remote, depending on the mobility or ptosis of the organ. Besides, gastroptosis rarely exists alone, but is accompanied with enteroptosis, gastric ectasia, etc. In these cases gastropexy is evidently insufficient.

Again he said:

> The operation is open to two other objections. The first is that, in fastening the pyloric end of the stomach in the epigastric region, we force the organ to bend itself, the median section not being brought back to the same level as the two tuberosities. The second objection is that the formation of adhesions between the stomach and the abdominal wall is not without inconvenience; therefore the operation presents serious chances of success only when the stomach is simply displaced. Even then it is doubtful if the operation will become popular.

It will be seen that the Duret operation was damned by faint praise, and, in effect, was killed where and when it should have been given serious consideration, for the patient was cured and lived many years in comfort. It remained for Professor Rovsing of Copenhagen to develop and extend the operation and prove to the profession that, contrary to any preconceived opinion, it should be given a trial. Rovsing has shown that in Denmark more than 256 gastropexies had been done up to 1911, and that cure, or great improvement, has been obtained in from 70 to 75 per cent., improvement in 10 to 12 per cent., no change in 11 to 12 per cent., and deaths in 3 to 5 per cent. These percentages are in round numbers

DESCRIPTION OF THE OPERATION

The usual incision for the stomach operation should be made, and should at least extend from the tip of the ensiform cartilage to the region of the umbilicus. The whole abdomen should be explored at once. The appendix should be removed if found diseased; the gallbladder emptied of stones if any are present, and excised if necessary; adhesions in any part should be examined, and eliminated if causing kinking or compression; the liver, if prolapsed, should be fixed by sutures to the peritoneal covering of the diaphragm, or the ligamentum teres should be severed and stitched to the diaphragm. Usually, the transverse colon must be brought into position by passing several sutures first through the serous coating of the colon, then in and out through the layers of the gastrocolic ligament, and finally through the serosa of the stomach along the greater curvature.

In doing this, one should be careful to avoid the blood vessels of the omentum. This brings the colon up close to the stomach. We are now ready to attach the stomach to the abdominal wall. I now give the peritoneum of the stomach and of the abdominal wall a good rubbing with dry gauze to cause roughness and exudation. Rovsing advises scratching these surfaces with a needle. Three heavy silk sutures are passed in and out through the serosa, each thread parallel with the axis of the stomach. These threads are about three-quarters inch apart; one just under the lesser curvature, one three-quarters inch below this, and one 1¼ inches above the greater curvature. The ends of the threads are passed entirely through the abdominal wall, at a distance of about 1½ inches from the median line. The wound is closed in the usual manner; a glass plate about 3 by 4 inches in size, wrapped in sterile gauze, is clapped on the abdomen, and over this the stitches are tied. This, of course, is done to bring a broad, flat surface of stomach against a similar surface of the abdominal wall. These threads remain undisturbed for four weeks or until complete convalescence has taken place.

CASE HISTORIES

Case 1.—The patient was successfully treated by advice, posture, and treatment of ethmoid sinusitis. Mrs. Dr. C., housewife, of Rochester, Ill. Parents living in good health. One sister living in good health. Aged 35 years. Married. No children. First saw her, Feb. 14, 1908. Had typhoid fever in 1895; very mild attack. Bowels constipated. Menses regular. First noticed particular stomach trouble some months ago. Has had numerous attacks of indigestion, which lasted ten to twelve days. There was no regularity about these. Her husband would give her medicine, but the attacks would recur. Average weight, 150; present weight, 115. No fever with attacks. No kidney trouble. No vomiting. Seems to be extreme burning in throat and stomach, which would last four hours and sometimes much longer. If she starves seems to be better. Thinks she has fallen off, because she eats nothing.

Examination shows no tenderness over the gallbladder or in the appendical region. Prolapse of the stomach is well marked. No floating kidney. Teeth good. Tongue in fair condition. Patient states she hurries to remove dishes from the table so that the dining room would look well when patients visited the doctor. Also at mealtime she would answer telephone in order that the doctor might eat without interruption. She eats rapidly. Advise that she stop answering the telephone at meals. Let husband attend to this, as he is sturdy and strong. That she cover the dining table with a clean cloth, and lie down after meals for a half hour with hot water bag to epigastric region. Gave diet, February 21. Thirty days later she reports she has had no burning of the stomach whatever. What she has eaten seems to agree with her. Has excellent appetite. Has gained in flesh. Bowels not so constipated. Nervousness better. Tongue is very clean. Now, 1917, nearly ten years after this advice was given, she tells me that her health has been excellent and she weighs 125 pounds. Health perfect except for occasional rheumatism.

Case 2.—Gastroptosis successfully treated by posture and bandage. Paul G., aged 18, student, of Springfield, Ill. He began to show signs of failure in strength and flesh, presumably as a result of overwork at school. This was not relieved by a change of climate, but emaciation progressed until his weight became 107 or less. Thorough examination shows negative Wassermann. No tuberculosis. Heart weak. Tonsils diseased. Stomach low down in pelvis so that the stomach, filled with bismuth milk, could be felt with the finger through the rectum. The tonsils were removed under local anesthesia. The patient was put to bed for ten days with the foot of the bed elevated 16 inches. A corset was applied to hold up the stomach, which was only partly effective because of the extreme emaciation. About this time an article appeared in the *New York Medical Journal* showing a bandage designed by Dr. A. E. Gallant of New York, and one of these was fitted to this patient. Proper exercise was prescribed to improve the abdominal muscles, and after four months the patient was allowed to resume his studies. The case has progressed favorably, and the patient's present weight is 143 pounds.

Recent fluoroscopic examination shows the stomach at least 6 inches out of the pelvis. The abdominal muscles are strong, and indications are that a cure has resulted. I can highly recommend the Gallant bandage when an operation has been performed and when an attempt is made to elevate the stomach without an operation. I have prescribed at least 100 of these, and I think some 700 have been prescribed in central Illinois. A large number of patients have been benefited by this simple appliance. They are cheap, cleanly, have no rubber elastic to wear out, and in all particulars have proved satisfactory.

Case 3.—Long standing stomach ailment due to gastroptosis successfully treated by direct Duret-Rovsing separation. Mrs. Theodore D., housewife, of Springfield, Ill.; aged 44; married; height 65 inches; weight 118 pounds; has weighed 145. Father died of typhoid, aged 30. Mother living in fair health. One brother living and healthy. Husband is living and in fair health. Three living healthy children. One infant died of erysipelas. No evidence of disease in mouth or air passages.

She says her abdominal symptoms date from the time when she clerked in a retail furniture store twenty years ago. Her hours of work were long; there was little time for meals; and she hurried back after eating, taking absolutely no rest after eating. She has had chronic constipation for years. She has taken a great deal of medicine for years, and lately has been confined to bed nearly all the time. Has had many spells of a hysterical nature, and has felt she would die, and has had a fear of falling all the time. She refused to go to the hospital for treatment. Her stomach has been washed out daily for two weeks without relief. She entered St. John's Hospital, June 13, 1917. Fluoroscopic examination shows the lower border of the stomach resting on the pelvic pan. The roentgenogram shows the characteristic stocking-shaped stomach.

Urine, 1.010, normal except a trace of indol; Wassermann, ++; blood, hemoglobin, 84; reds, 5,100,000; whites, 7,800; differential, 64 and 36. She was given four intravenous injections of arsphenamin, total amount 0.90, and four deep injections of mercuric salicylate, total 40 minims; and was given also two teaspoonfuls of mistura rhei et sodae in hot water before meals. No relief from vomiting, which was of daily occurrence. Finally she was deprived of all nourishment by the mouth, and given rectal feeding only. Vomiting began again after a few days. Her weight was reduced to 96 pounds, and the outlook was quite unfavorable.

A Rovsing operation was done, July 24, Dr. Kelly assisting. An incision was made from the sternum nearly to the pubes. Marked prolapse of the liver was found, marked adhesions about the gallbladder, and marked enlargement and prolapse of the stomach and colon. There was no disease of the gallbladder or of the appendix. The other organs appeared normal, and there was no apparent ulceration or disease of the stomach. Under these circumstances it was decided to break up all the old adhesions, and to anchor the stomach in its normal position as well as possible by the Rovsing method. The anterior surface of the stomach and the peritoneum of the abdominal wall were rubbed. Two of these complete sutures through the abdominal wall were inserted. The ascending colon by stitches through the abdominal wall was anchored in nearly the normal position. Another suture was placed about the middle of the transverse colon. A third suture was not placed in the pyloric region of the stomach because of the prolapsed liver. The patient left the table in good condition.

Vomiting began again the third day after operation, and was so violent that the lower part of the incision was opened. Owing to the critical condition of the patient the small intestine, which had prolapsed through the wound, was merely pushed back, and the wound drawn together with adhesive strapping and allowed to heal by granulation. Undoubtedly, there is a considerable adhesion at this point. She left the hospital, September 16, about seven weeks after the operation.

Her recovery has been slow, but steady, and she now weighs 130 pounds, a gain of 35 pounds. Her bowels move each day without a cathartic. She has an excellent appetite. She declares herself entirely well, and seems to be.

The patient was interviewed, May 20, 1918, and seemed well in every way except for occasional nervousness.

CASE 4.—Long standing stomach ailment due to gastroptosis successfully treated by Duret-Rovsing operation. Miss Hattie H., aged 49, housewife, of Waverly, Ill., weight, 94 pounds; entered hospital, Oct. 15, 1917. Family history rather negative. Father died of kidney disease at age of 70; mother died of heart disease at age of 63. One brother died of tuberculosis; one brother suicide at age of 37; one brother died a soldier in the Philippine Islands; one sister died in childbirth; one sister living at 27 is very nervous; four brothers are living in fair health.

She has had stomach trouble for thirty years. More particularly has suffered in the last six or eight years. Always had pains after meals. The last three weeks has taken only egg water and ice cream. A prominent physician in a neighboring city thought she had gallbladder trouble, and treated her for about one year.

On entrance she was so weak that it was necessary to have a sister support her on each side to get a fluoroscopic examination of the stomach. Examination resulted as follows: Wassermann, negative.

Urine: Specific gravity, 1.030; acid; otherwise negative. Blood: 66, 29, 4, 1; reds, 4,040,000; whites, 6,600; hemoglobin, 80. Feces: no blood; no ova; no tuberculosis; no parasites. Stomach contents: mucus on top; micro, negative; food, well digested. Free hydrochloric, 25; organic, 18; total acid, 55; comp. hydro, 15.

Fluoroscopic examination revealed a ragged outline of the stomach, which fails to empty after seven hours. The bowels are much distended with gas. There is also an infiltration in the lower left quadrant of the stomach which is associated with the infiltrated liver. The heart is somewhat atrophied. The stomach shows a very large amount of gas. The lower border extends down to 2 inches below the crest of the ilium. There seems to be considerable fixation of the tissues of the abdomen. There appeared to be a large amount of fluid in the stomach besides the fluid that had been ingested with the meal.

All conditions being considered, it was thought best to suggest an operation, which was agreed to on the theory that death was better than a continuance of life under the present conditions.

Operation was performed, Nov. 3, 1917. An incision was made from the sternum to below the umbilicus. The liver seemed prolapsed. The gallbladder was examined and found empty. The appendix seemed distended, and was removed. The transverse collapsed colon was sewed to the lower border of the stomach. Three sutures were placed according to Rovsing. The liver was displaced downward and would have been attached to the diaphragm had not the patient shown symptoms of collapse. The wound was brought together, and linen threads (not too heavy) were tied over the glass plate. Two small fibroid growths on the uterus were not removed. The ligatures through the stomach were removed at the end of twenty-three days.

The convalescence was unexpectedly rapid and satisfactory. This patient was seen July 22, 1918. She is keeping house for a brother and seems entirely free of her abdominal and nervous symptoms.

ABSTRACT OF DISCUSSION

DR. CARL E. BLACK, Jacksonville, Ill.: Since we are able to make roentgen-ray studies of these cases, the number has no doubt greatly increased. If anything can be done to take these cases out of the classification of neurasthenics and hysterics, give them a real pathologic basis and put the patients on a plan of treatment which will lead to a reasonable percentage of success, great good will be accomplished. I have been watching Dr. Kreider's cases and have been led to believe that a number of these patients should be treated with the Rovsing operation. The difficulty that I have is to know how to differentiate them. It is rare that there is simply a ptosis of the stomach and transverse colon. Usually the ptosis is more extensive than that, and combined with it there is usually a history of infection, which, no doubt, in a large percentage of cases, is an underlying factor. These patients are weakened by chronic infection, and the ptosis comes on gradually and insidiously following an infection. That infection may be in the abdomen or elsewhere. In the treatment of these patients it is necessary, first of all, to clear up as nearly as possible all of the foci of infection. I have seen a number of cases where by operating on the gallbladder or the appendix, especially an old chronic appendix with many adhesions, the symptoms disappear, although nothing was done for the ptosis. Some of the most startling successes I have had were achieved by putting these patients to bed, raising the foot of the bed and keeping them there six to eight weeks, following that by the use of a belt for support after they have gained 20, 30 or 40 pounds. One man treated in that way gained 45 pounds after eight or nine months, and now appears to be perfectly well. In that case the difficulty was largely aggravated by a bad habit of taking a quart or more of water the first thing in the morning. He seemed to think that he must drink water by the quart because he had certain digestive symptoms which undoubtedly aggravated his condition.

DR. GEORGE P. MÜLLER, Philadelphia: Dr. Kreider uses the term splanchnoptosis to cover the symptomatology of the type of cases referred to in his paper, and apparently advocates its treatment by suspending the stomach by the Rovsing operation. I believe it is necessary to take a more comprehensive view of the subject and to understand and distinguish between ptosis of the stomach, colon, kidney, cecum, etc. I believe that in the majority of cases the various types of visceroptosis are of congenital origin, and are not acquired by the wearing of tight corsets, high-heeled shoes, by faulty teeth, etc.; while these may bring on the symptoms due to the ptotic state. Some patients have ptosis of certain of the abdominal organs with gastric symptoms. Obviously, it is necessary to know whether the ptotic stomach per se is causing the gastric symptoms, or whether these are reflex to a retroverted uterus, to a mobile kidney, etc. I do not think much of the Rovsing operation, but prefer the Beyea operation, properly performed, and, in any event, do not do these operations unless careful roentgen-ray studies have shown that the ptotic stomach is of the so-called water-trap form, and is causing the symptoms from which the patient suffers.

DR. GEORGE N. KREIDER, Springfield, Ill.: I ask you to make in your nervous cases an *observation* of the stomach with the fluoroscope or roentgenograph, and you will get many surprises by finding that ptosis lies at the base of many nervous troubles, which are absolutely cured by this simple operation, or better still, without operation. I said distinctly, "Never operate on these patients if they can possibly be helped otherwise."

Reclassification of Athletics.—In a word, all branches of athletics must be reclassified on the basis of their effects on the heart and other vital organs, and we must discard the old classification based on popularity and commercial advantage. In the grammar school the form of athletics to which a boy could be assigned or which he would be permitted to engage in would depend on (1) his family history; (2) his personal history, having regard especially to previous illnesses endured; (3) his physical status; (4) his particular type, height, weight, etc., in relation to age, etc. Every class would have its specially prescribed athletics, both physical and tactical, and under no circumstances would a lad be allowed to engage in competitive sports assigned to a class above or below his own. A physical examination would mark his entry to and exit from a class and he would be marked for development of body and for ability to perform the various tactics. While in the grammar school a chart would be begun for him which would accompany him throughout his educational career.—Lieut. D. F. Luby, *Naval Medical Bulletin*, October, 1918.

COMPARATIVE VALUE OF IPECAC AND ITS ALKALOIDS IN TREATMENT OF INTESTINAL ENDAMEBIASIS *

SIDNEY K. SIMON, M.D.
Assistant Professor of Clinical Medicine, Tulane University of Louisiana
NEW ORLEANS

There is universal concurrence of opinion at the present time in regard to the highly specific effect of ipecac, as well as of its constituent alkaloids, on the vegetative forms of the pathogenic endameba. Though the ipecacuanha plant, and especially its root, has been employed since remote times as an empiric remedy in the treatment of many varieties of intestinal disorders, it is only within comparatively recent years that recognition of its sole and distinctive value in endamebic disease has been definitely reached.

An interesting and diversified history surrounds the earlier use of ipecac as a therapeutic agent, traceable back as far even as the beginning of the Middle Ages. It was first introduced into Europe in 1648 in the guise of a secret remedy for dysentery, having gained considerable repute originally among the natives of Brazil for its usefulness in this class of affections. The story is related that the French government, impressed by the striking results obtained in the case of the Dauphin, son of Louis XIV, then reigning, was induced to purchase the secrets of the wonderful remedy outright, for universal dissemination. In the course of the years that have since followed, reaching to the present day, ipecac, in some one of its many forms, has weathered a shifting reputation for dependability in dysenteric disturbances, being lauded and denounced in turn by various authorities in almost as many climes.

During the period immediately preceding the close of the last century, the drug had fallen into almost complete disuse, doubtless because of the disagreeable effects which so often attended its administration. In the eyes of the more careful English observers in the tropics, however, ipecac had always maintained the foremost place as an indispensable measure for combating the dysenteries of warm countries, especially in India, and it is, in fact, due largely to the earnest pleas of this school, headed by the venerable Sir Patrick Manson, that credit should be accorded for rescuing the drug within recent years from all but entire oblivion.

Some ten years ago, being impressed by the weight of this authoritative experience and especially after I had previously convinced myself of the noneffectiveness of the various measures then in vogue against the all too prevalent endamebic infections in the South, I[1] ventured to make trial of the old-time ipecac treatment. The powdered root, made into pill form, was employed for the purpose, each pill being provided with an enteric coating of salol, in accordance with a previous suggestion of Rogers. The striking results which attended the trial of this treatment in a series of about fifty cases were subsequently summarized in a report read before this Association in 1909. A short time previous, George Dock[2] was able to report equally favorable results from observations made independently in the same field. Though confirmation of these experiences was soon recorded from numerous sources, objection to the method was raised on many sides mainly on the grounds of the clinical difficulties involved in the administration of large numbers of pills at one time, many of which were found not infrequently to pass through the bowel without dissolving. Likewise, the failure to control nausea and vomiting in some patients, in spite of a liberal enteric coating of the pill, called for additional unfavorable comment. These difficulties, which even today are still not entirely under satisfactory control, served at the time to disqualify the procedure in the eyes of a considerable element of the profession. Demand was made for a less cumbersome manner of employing the curative features of ipecac without entailing such great discomfort to the patient. The answer to this demand was not long withheld. In 1911, Vedder[3] and subsequently Rogers[4] were both able to report success in the therapy of endamebic infections with the use of emetin, an alkaloid derived directly from the crude ipecac root. This substance, in the form of the hydrochlorid salt, they found to be especially adapted to hypodermic administration and only rarely was emesis found to occur with its use. Likewise its prompt action on the clinical disturbances of the disease was most striking, and within a very short time the virtues of the parent drug were all but completely overshadowed and forgotten. With the course of time, however, evidence has accumulated which has tended to throw more and more doubt on the justice of many of the early claims regarding the superiority of emetins over the entire ipecac root, especially in the control of the more chronic and intractable endamebic infections. While no question can be raised of the prompt amebicidal action of emetin on the free living or vegetative organisms, more extended opportunity for observation has made it increasingly clear that, in the matter of the destruction of the endamebic cysts, the alkaloidal therapy in many instances meets with marked failures, thereby opening the way for repeated recurrences of the infection. A recasting of the earlier and more optimistic views, especially in regard to the absolute and complete specificity of emetin in endamebic disease would therefore seem to be necessary.

INADEQUACY OF EMETIN

Vedder,[5] himself, as early as 1913, was willing to admit that "a large percentage of cases treated with emetin continued to harbor the *Endameba hystolytica* in the encysted and most dangerous form in the feces for some time." Likewise Allan,[6] Baermann,[7] Gaide and Mouzels,[8] and Marchoux,[9] each have reported in turn unfavorable results from their experience with the emetin treatment alone, claiming that "the endameba were not expelled from the intestinal tract to the degree that the relief of clinical symptoms would lead one to expect." Still more recently, Phillips[10] concluded an excellent review of the subject with the statement that "the effects of emetin are not permanent and that though the active amebia are killed off very quickly, the drug has no effect on the cysts." Again, G. I. Jones[11] says significantly; in summarizing a large number of cases placed at his disposal, that while he considers emetin a valuable agent in the treatment of intestinal amebiasis, "the use of this drug alone will not cure amebic dysentery." This author found, in fact, that relapses soon occurred and strongly urged the employment of ipecac by mouth, as a necessary step in the achievement of complete and permanent recovery. The results of these, as likewise of numerous similar observations which have been recorded in the literature with increasing frequency in recent years would seem to point unmistakably to the conclusion that, while emetin does prove of undoubted service in the destruction of the free living endamebas, it finds a greatly restricted field of usefulness in the all-important matter of the removal of the cysts from the intestinal tract.

A close analogy exists, in fact, between the *Endameba histolytica* and the malarial hematozoa in the matter of their behavior to specific medication. Both organisms, in common with protozoa in general, exhibit two separate and distinct phases in their life cycle, including a free living or vegetative stage of existence which permits of free locomotion enabling the cell to obtain its nutriment, and a second state in which the vital activities of the cell are found in abeyance within the enclosure of a cyst wall (the so-called gamete). It is only in the latter state that infection is conveyed from host to host, since the vegetative organism is prone to succumb or to undergo encystment when removed from its original environment. The pathologic conditions arising in the human organism are, however, the sole result of the vital manifestations of the free living protozoon. In its encysted state the organism lies dormant, incapable of tissue harm, but offering marked resistance to external influences. It is most important to understand, in this connection, that the protozoa, once having become encysted, have acquired thereby an increased resistance to their specific drug, in sharp contrast to the ease with which the organism in its vegetative state may be reached and destroyed in the same dosage. In fact, relatively small amounts of the specific drug, instead of killing the organism outright, will often induce the obverse effect of driving it into encystment. While the immediate clinical symptoms are promptly relieved by such a process, the difficulties surrounding the complete eradication of the infection are largely increased. In regard to malarial infections, the fact has already been well established, that relatively small amounts of quinin tend to encourage the formation of gametes. Similarly, in endamebic disease, unless appreciably large doses of ipecac or of its alkaloids are employed, the free living organism seeks protection against the toxic action of the drug by enclosing itself within a cyst wall.

In the dosage found necessary for the complete overwhelming of the offending organisms, consideration must be given to the matter of the toxicity of the drug itself on the human host. While the crude ipecac, in amounts as high as 75 grains in daily doses repeated over a period of ten days, has been found singularly devoid of toxic effects, experience has shown that the alkaloids, in an equivalent dosage, possess no such immunity.

RESULTS OF INVESTIGATIONS

As far back as 1817, investigations into the pharmacology of ipecac had been made by Pelletier,[12] a French chemist. Pelletier believed that the root contained but one alkaloid, to which the name emetin was applied as a fit designation for the emetic properties exhibited by the drug. It was not until 1894 that Paul and Crownley[13] were able to show that the root contained a second active alkaloid, to which the term cephaelin was given. Subsequently, still another alkaloid, psychotrin, has been identified and it is not improbable that the future may reveal the presence of yet another derivative. In 1895, Wild[14] made an exhaustive study of the poisonous effect of both emetin and cephaelin on the human organism, as well as on some of the lower animals. Numerous other observations have been contributed within more recent years, serving further to enlarge our knowledge of this important subject. Perhaps the most notable among these have been the series of extensive experiments conducted by Pellini and Wallace[15] in 1916 into the various toxic effects produced by emetin on the various organs of the body. As a result of their findings, they were able to formulate the following conclusions:

1. Emetin depresses, and may eventually paralyze the heart.
2. It is a powerful gastro-intestinal irritant, whether given by mouth or by subcutaneous injection.
3. It causes a definite derangement of metabolism characterized by an increase in nitrogen loss and an acidosis.
4. While in normal individuals, given moderate doses, these actions may not be of importance, in pathologic states of the circulation, intestinal tract, or metabolism, there may be a very definite source of danger.

While it is true markedly poisonous effects are rarely observed in connection with the comparatively small doses of emetin ordinarily employed in clinical practice, milder types of toxemia are by no means uncommonly encountered. Lyons,[16] for example, as early as 1915, pointed out the not infrequent occurrence of a peripheral neuritis in the course of the ordinary subcutaneous administration of emetin. In my opinion, this complication may take place even with very small doses of the drug and, while rarely of a serious character, may nevertheless give rise to a considerable degree of pain and muscular discomfort. Other sequelae resulting from the use of emetin in average doses from time to time have been recorded in the literature, such as an intractable form of watery diarrhea, gastric hyperemia and irritability, cardiac arrhythmia, including in addition the various types of skin reactions which frequently appear at the site of the injection of the drug.

The investigations made in regard to the toxicology of cephaelin hydrochlorid, while not carried out on as extensive a scale as has been the case with emetin, have nevertheless revealed a close similarity in the physiologic action of the two alkaloids. Cephaelin has been shown to possess greater emetic properties and is far more irritating to the skin when given hypodermically than is emetin. Its destructive effects on the vegetative endameba is probably equally as great as that of emetin. This was strongly indicated in the course of some clinical experiments I was enabled to make three years ago[17] on a limited number of adult subjects suffering with active intestinal amebiasis. However, the same failure in the matter of the destruction of the cysts was noted, as had been my experience previously with the emetin therapy.

Because of the failure of the ipecac alkaloids to remove encysted ameba from the tissues, and likewise in consideration of the toxic properties which have been shown to be inherent in these agents, attempts have been made recently to devise higher chemical formulas of the alkaloids which, it was thought, might overcome the various objectionable features of the simpler products.

Of these compounds perhaps the two most widely employed have been emetin mercuric iodid and emetin bismuthous iodid, prepared in accordance with definite formulas suggested by DuMez[18] in 1915. These substances were designed for oral administration and, because of their relative insolubility, it was hoped that their emetic effect might be reduced to a minimum. However, according to most observers, this hope has scarcely been realized. Much favorable comment has nevertheless appeared in the recent literature, emanating principally from British sources, extolling the special virtue of these preparations in the more intractable forms of endamebic dysentery and claiming a particular influence in the extermination of the carriers.

In this country, Walters and Koch[19] have recently published the results of experimental work carried on by them with synthetic derivatives of cephaelin, citing with particular favor cephaelin iso-amyl ether hydroiodid. They found this substance uniformly effective in destroying both the vegetative and the encystic endameba in the intestinal tract of cats. I have availed myself of the opportunity offered by Dr. Walters of trying out this preparation on human subjects, three in all, each presenting outspoken chronic endamebic infection of the bowel. Its action on the free living endameba proved it to be equal in value to that of the simple alkaloids, but again no definite effect could be noted in its action on the cysts. The dose employed was from ⅓ to ⅔ grain, three times a day in capsules by the mouth, and the treatment was made to cover a period of ten days in each case.

IPECAC TREATMENT

In view of the evident inadequacy of the akaloidal therapy and its failure effectually to destroy the endameba, once they have reached the encysted state, the conviction has grown increasingly strong with me that a return to the use of the original crude ipecac root should be most seriously considered by the profession at the present time. In my hands the plan first announced in 1909 of making use of ipecac in the form of enteric-coated pills has continued to yield uniformly gratifying results, both in meeting the active clinical manifestations of the disease processes and above all and perhaps of greatest importance, in the almost certain prevention of relapses which is achieved. The careful attention to detail which has been found so necessary to this plan of treatment, and which has unfortunately been an object of neglect on many sides in the past, would seem to justify a further word of explanation and emphasis at this time. The failure to observe the smaller details of the plan has been the cause, in fact, of much of the former prejudice surrounding the administration of the crude ipecac. First of all, it is essential that the patient be put to bed for the full course of the treatment, extending ordinarily over a period of ten days, and also that the dietary be restricted in the beginning to articles of food which leave no residue in the intestinal tract, such as broths, whey, albumin water and the various nutrient alcoholic preparations. To this list, milk is to be added only after the fifth or sixth day of treatment. A dose of castor oil should be administered on the morning of the first day of treatment and in the evening around 9 o'clock, from ten to fifteen salol-coated pills should be taken, each containing 5 grains of the powdered ipecac. The patient is advised to swallow these slowly with the help of moderate amounts of water. No nourishment is allowed for two hours preceding and likewise for six hours following the administration of the pills. Each succeeding night the same plan is to be repeated, the number of pills varying on each occasion from ten to fifteen. It may be found necessary, especially in the presence of any depressing effect, to discontinue the use of the pills for a one-night period. Each day the attending nurse keeps a record of the number of pills which might have passed undissolved in the stool, with the view of determining the total amount of ipecac retained at any stage of the treatment. A simple method of daily charting, illustrated in the accompanying table, has been devised by us for this purpose.

AMOUNT OF IPECAC ADMINISTERED AND RETAINED DAILY

Date	Pills Administered	Pills Found Undissolved in Stools	Pills Retained
Jan. 1	15	0	15
Jan. 2	15	2	28
Jan. 3	14	3	41

The complete dosage includes the retention of at least 100 pills, equivalent to 500 grains of the powdered ipecac. This is accomplished usually within a period of ten days and only under rare conditions must be made to extend over two weeks. Should nausea and vomiting arise as troublesome features, an extra enteric coating should be added to the pills. We have found that, under average conditions, a coating of one tenth inch of salol is ample. For reasons not altogether clear, it may happen that large numbers of the pills will pass through the intestinal tract in an undissolved state, even in spite of a diminished enteric coating. Under these circumstances, we frequently adopt the plan of making from one or two small punctures into the outer layers of the pill surface, with a small sized surgical needle. When, under rare conditions, the ipecac will not be tolerated in pill form by the patient, we may often successfully substitute the duodenal intubation method, employing for the purpose daily installations of 30 grains of the powdered ipecac suspended in water.

SUPERIORITY OF IPECAC

There remains to be considered finally the essential cause for the superior effectiveness shown by the entire ipecac root in the treatment of intestinal amebiasis, as compared with its constituent alkaloidal derivatives. From the standpoint of analogy with other therapeutic agents, it would seem that the active principles would, at least, possess a value equal to that of the parent substance. However, in the matter of the control of a protracted endamebic infection of the bowel, conditions of a somewhat anomalous nature are presented. The crux of the problem, to my mind, hinges on the question of the degree of concentration of the active constituents of the specific drug at the site of infection in the large bowel. When the alkaloids are administered by hypodermic injection or by mouth within the confined limits of safety, the attenuation that results in the blood stream renders the drug relatively inert when brought to bear on the infecting organisms in the intestinal wall. Under the influence of a weak dilution, the endamebas escape immediate destruction by seeking cover, so to speak, within a resistant cyst wall. Were it possible to employ massive doses of the alkaloid, prompt and rapid annihilation of the endameba might be expected to ensue. The toxic character exhibited by these substances in excessive amounts precludes, however, the employment of a large dosage. With the use of the ipecac mass orally, in daily amounts as high as 75 grains and yielding approximately 1.5 grains of total alkaloids, a concentration of the effective properties of the drug is attained in the infected colon, without any possible danger of toxemia. The patient's intestinal tract, having been rendered free by dietary restrictions, as explained in the foregoing, the pills pass quickly into the large bowel, where the salol coating is finally dissolved away in its entirety and the ipecac thus set free for absorption. It may be considered that soluble compounds of the alkaloids are formed directly within the colon, and during the process of absorption not only the vegetative endameba, but the encysted forms as well, suffer destruction in the concentrated medium. Apart from whether this explanation be considered adequate or not, it is my firm conviction, based on clinical observations extending now over several years, that the treatment of intestinal endamebiasis by means of the crude ipecac offers a most promising outlook for complete and permanent cure, not attainable with the use of the alkaloids alone, whether administered orally or hypodermically.

CONCLUSIONS

1. Both ipecac and its constituent alkaloidal derivatives, emetin and cephaelin, have been found to act specifically on the vegetative or free living forms of the *Endameba histolytica*.

2. The crude ipecac root in doses sufficient completely to destroy the infecting organisms is never toxic.

3. Both emetin and cephaelin frequently exhibit toxic properties in an average dosage of from 0.5 to 1 grain daily over a limited period.

4. The alkaloids alone are ineffective within safe limits of dosage in destroying the encysted forms of the *Endameba histolytica*.

5. The entire ipecac root, when employed under proper conditions, not only destroys the vegetative endameba but the encysted forms as well, and thereby prevents recurrences or relapses of the infection.

ABSTRACT OF DISCUSSION

Dr. Frank Smithies, Chicago: I agree with Dr. Simon that the use of crude ipecac has been effectual in the treatment of acute or chronic enterocolonic amebiasis. Perhaps Dr. Simon unintentionally neglected to state that there are instances where emetin is also of service. I came to the conclusion some years ago that large doses of ipecac administered after the method described by Dr. Simon and first suggested by Dock, aided in quickly ridding the terminal ileum and the colon of organisms, if emetin be given hypodermically at the same time. Dr. Simon explained the reason for large doses of ipecac, namely, to obtain a continued saturation of the bowel contents with the drug. Often encysted or active amebas are deep within the mucous membrane of the intestinal wall. A medicine solely in the bowel cannot reach them and consequently does *not* kill them. It is in this class of case that it is necessary to carry the amebacide to the organism by means of the lymph or the blood stream; therefore, it is necessary to combine the ipecac treatment with emetin given hypodermically. Unless this is done, the bowel contents will be rid of protozoa but the organisms already in the wall of the intestine will carry on their destructive work. If one uses emetin alone, and neglects to use the ipecac saturation of bowel contents, it is self-evident that sooner or later the ulcers free from amebas will become reinfected from the bowel contents. The combined treatment is successful in curing the majority of patients, and prevents recurrences.

In respect to recurrences, I would emphasize the frequent finding of viable or encysted amebas in the gallbladder, appendix or old, partly healed intestinal ulcers. In these cases it sometimes is possible to remove the foci of infection surgically. I have seen several cases where there was complete recovery after the removal of the gallbladder. Further, it is my opinion that patients are too often pronounced cured; that the stools are not examined for a sufficiently long time after the administration of specific medication. Viable amebas and cysts are often present in the stools when the individual is symptomatically well. We have the patients return once every two or three months for reexamination of freshly passed stools. We never use castor oil as a preliminary cathartic but rather a saline. This enables the exact examination of the stool microscopically.

Recently we have been using ipecac by a new method, namely, the introduction of from 2 to 4 ounces of wine of ipecac directly into the colon by rectum. This has been effective where other methods of giving ipecac have failed. We have recently had two patients under observation in whom almost constant hemorrhage produced severe anemia. In this class of case we have employed transfusion of large quantities of whole blood beneficially. This procedure should be employed more frequently in order to increase tissue defense in severe amebic enterocolitis.

Dr. Hugo A. Freund, Detroit: My observations bear out what Dr. Simon said, that occasionally patients do not respond to ipecac. Having had a somewhat unsatisfactory experience with emetin and a very happy experience with ipecac, I thought of using the duodenal tube to give the wine of ipecac, preparing the patients much the same as Dr. Simon has suggested, except that at the end of about three days I give them a small dose of opium in some form to quiet them, so they will probably be constipated for two or three days following. I pass the duodenal tube on an empty stomach, and then inject the wine of ipecac. By the instillation of relatively large doses I get satisfactory results, beginning the first day by giving 1 ounce, the next day 2, and so on. I have given as high as 6 ounces in one instillation. I have had very satisfactory results in the fourteen cases I treated by this method. I reexamine them every three months, looking for encysted forms; and I have not seen a single relapse.

Dr. Horace W. Soper, St. Louis: Since I adopted the use of emetin intravenously I have had fewer relapses. Two cases of neuritis developed, but they were mild, and very soon subsided. The emetin is injected in 1-grain doses, until the lesions have cleared up, as demonstrated by the sigmoidoscope. The lesions are very characteristic, small, elevated, grayish patches, which, when wiped off, leave a little bloody spot. The viscid mucus in these patches shows almost a pure culture of ameba. So that in the treatment of these cases we watch the lesions, and discontinue the emetin when the case is clinically improved. I give it once a week for two months, hoping to catch the encysted forms at the time of their development. The ipecac as used by Dr. Simon presents some disadvantages, inasmuch as the pills are very difficult to make. Dr. Simon's pharmacist has, perhaps, solved that problem. Some years ago I was unable to get a pill that would not cause nausea or that would not dissolve in the intestinal tract.

Dr. Sidney K. Simon, New Orleans: The whole aim in the treatment of an endamebic infection lies in the removal of the cysts. The destruction of the vegetative forms alone, with the relief of clinical symptoms that follows, is in itself rarely a difficult problem. Putting the patient to bed for a period of a few days will usually suffice to relieve the immediate clinical distress even without the aid of other measures. It is only in the complete destruction of the encysted forms, however, that relapses can be prevented and a permanent cure established.

In regard to the examination of the stools, we long ago adopted the proctoscopic method in all cases of suspected protozoon infection. In this way the smears are made directly from ulcerated or denuded spots on the rectal mucosa, without the necessity of having the stools conveyed in bulk. The severe grades of anemia represent the end result of a protracted endamebic infection. With specific medication such a complication should rarely be observed. In the last few years, I have seen very few instances of severe anemia among my endameba cases.

Dr. Freund's ipecac method I intend to keep in mind. However, since the method I have described this morning has been uniformly successful as a curative measure in fully 500 cases, with very infrequent, if any, relapses, other plans do not, of course, make strong appeal. In regard to the intravenous injections of emetin hydrochlorid, mentioned by Dr. Soper, I would wish to advise caution. Such a procedure, especially in the hands of the less experienced, would be capable, I think, of much abuse.

The point Dr. Soper made concerning the availability of the salol coated ipecac pill has been a bone of contention ever since the method of treatment was inaugurated. Any competent pharmacist should be able to dispense these pills satisfactorily. However, a certain amount of technic is required which the average druggist does not seem to have acquired. The pills cannot be produced in bulk by the manufacturing pharmaceutical houses, because of the fully demonstrated lack of durability of the product. The pills must be made by the individual druggist and dispensed in quantities sufficient only for the individual case.

FOCAL INFECTIONS OF THE EYE FROM THE INTESTINAL TRACT *

JAMES GARFIELD DWYER, M.A., M.D.
NEW YORK

During the last few years marked attention has been paid to the consideration of infections of various parts of the body, due to a low-grade chronic infection in other parts, especially in the teeth and the tonsils. A very considerable advance has been made in the treatment of these so-called focal infections by the treatment of the original foci. The number of such cases on record is enormous and is fast increasing, and nowadays with certain infections we look for the primary cause and eradicate it if possible. Among these focal infections are some lesions of the eye that used to be grouped under a general classification, as "rheumatism," etc. We know now that there is probably no such disease as rheumatism per se, but that the symptoms classified as rheumatism are probably manifestations of some focus of infection. The work on focal infections of the eye, due to infections of the teeth and tonsils, has been reported by many observers and need not be touched on. This paper will deal with focal infections of the eye, due in all probability to the absorption of toxins from the intestinal tract. A few suggestions will also be made as to the method of treatment now being given a trial in order to overcome these infections, since it is impossible to treat the intestine surgically in the same way teeth and tonsils are treated.

This investigation has been going on for about two years, and any statements that are made are the outcome of what we have learned in that time, and are subject to change in the future. The whole idea of presenting the paper now is to direct attention to such infections and to possible methods of treating them.

At the beginning I was confronted with the fact that no two authorities were agreed as to what the intestinal contents in general should be; that is, the reaction, the amount of chemical constituents, the food detritus and the bacteriologic content. This was and still is a great difficulty. Some may question my interpretation of what normal intestinal contents should be, but from an examination of hundreds of samples, I have come to look for certain main characteristics.

Practically all authorities agree that normal feces is faintly alkaline to litmus, but litmus is a rough and ready method of taking the titration. With phenolphthalein the reaction is slightly acid, but only with fresh feces, because the reaction changes very rapidly on standing. The question of reaction is a very important one and one not easy to decide, as the end-point of acidity of alkalinity varies with the indicator used, namely, litmus, methyl orange, plenolphthalein, etc.

Just as in diabetes and nephritis the modern schools of medicine are aiming to test the efficiency of the body to assimilate the three food elements, namely, fats, carbohydrates and proteins, so I examined the detritus, keeping these three fundamental bases in mind. My guiding principle was to cut out of the diet the types of food that were not being assimilated, in other words, food elements whose by-products are indol, skatol and phenol. These products are normally present and unless abnormal in amount can be disregarded, but as the former two are known to be absorbed into the system, appearing as indican in the urine, and as they are products of protein metabolism, I paid special attention to them, as will be noted later.

BACTERIOLOGY

Here I was confronted with the biggest problem of all, as the intestine normally contains many and various forms of bacteria. I made no endeavor to identify the various forms of bacteria present, as that would have been impossible; but bearing in mind the work of various investigators, especially Metchnikoff, I paid special attention to the presence or absence of the colon bacillus. Now, the colon bacillus appears in the intestine a few days after birth, and is usually found there throughout life. Again, the colon bacillus is gram negative, that is, it stains a different color from that of the other bacteria usually found, the latter being gram positive with very few exceptions. Hence we have a ready means of comparison. The ptomain producers are usually gram-positive large bacilli, producing either acid or alkali, according to the group. Many of them are of the anaerobic varieties, such as the *Bacillus aerogenes-capsulatus*.

Keeping these facts in mind and trying to narrow the whole affair down to a practical working basis, I carried out the following routine: The intestinal contents were examined as to their reaction, their content of indol and skatol, the food residue and the bacteria. Besides these cardinal principles, other side factors were noted. If the contents were found to be practically normal, these were noted as controls. In most of the patients examined, the contents could be classified under two headings, as to whether they were highly acid or alkaline. In both classes, the colon bacilli were either entirely absent or present only in very small numbers, the other bacteria being practically gram positive. This was true whether the reaction was to either extreme, since the colon bacillus cannot live in a highly acid medium, although it is an acid producer, and of course it is killed off in alkaline mediums. It was always found that in both highly acid and highly alkaline specimens the indol and skatol content was high, and there was always a high percentage of indican in the urine.

---

* Read before the Section on Ophthalmology at the Sixty-Ninth Annual Session of the American Medical Association, Chicago, June, 1918.

The following methods of treatment were then adopted. In the highly acid specimens, an endeavor was made to alkalize the contents by the use of irrigations of a 1 per cent. sodium carbonate solution and then to practice colon transplantation in order to approach the normal. At the same time the patients were put on rather free diet, cutting out those foods that were not completely assimilated, such as meat. In other words, the tolerance for the three fundamental foods was established as far as possible. In the highly alkaline specimens, irrigations with lactose were given and then the colon bacillus was transplanted. At the same time the Bulgarian bacilli were given by mouth, the whole idea being to approach the average normal. Lactose was also administered by mouth in such cases to provide a suitable pabulum for the colon bacilli. At stated intervals, examinations were made and the treatment was repeated until I got a good growth of colon bacilli.

The types of cases I have chosen to be reported are those that would not respond to any other form of treatment—cases in which the patients were thought to be focally infected, although treatment of the teeth and tonsils proved unavailing. They are all cases that had lasted for weeks, the patients being better one day and worse another, showing no real improvement.

REPORT OF CASES

Case 1.—Charles B. had lost the sight of the right eye on account of a low grade ulcerative keratitis that had lasted six months and left the eye in a badly damaged condition, with the pupillary area of the cornea covered with a macular scar. He had been treated for this eye by some of the best ophthalmologists in the city and had been an in-patient at one of our hospitals for weeks. When I saw him, he had been in our wards for some weeks with the same condition in the other eye, the history of this lesion dating back two months. Every test had been negative and he was put on antispecific treatment, as it seemed the most promising remedy. On taking his history, I elicited the fact that he had had intestinal poisoning for years and could not get any relief. He volunteered the information that the other eye had become quiet as soon as he had gone to a stomach specialist. At first examination, the condition of the eye revealed a diffuse low grade keratitis, with a low grade iridocyclitis. In spite of all measures, the pupil could not be kept dilated but would dilate under the atropin and then contract again. One noticeable point was that the man's face was covered with acne rosacea. Immediate examination of the intestinal contents revealed a reaction highly alkaline, indol and skatol ++++, and bacterial smears totally gram positive. The treatment outlined in the foregoing was carried out, and within two days, the condition of the eye was much better, the pupil remaining dilated under cycloplegia. Within a week he went home with a perfectly quiet eye. The acne cleared up and when he last reported, after six months, he was in excellent condition, with a perfectly serviceable eye.

Case 2.—J. Mc., a man, had suffered nine months from a plastic iritis of low grade in both eyes, which kept him from business and made a semi-invalid of him. He had been under the care of competent ophthalmologists in the city, had had his teeth roentgenographed and the diseased teeth removed, and had had his tonsils out, yet the condition persisted. The same condition was found here. Within eight days the eyes had quieted down and, according to the last report I had, some months after the lesion, he was in excellent condition.

Case 3.—Mr. S., Orange, N. J., consulted me about his eye. He was suffering from an intense plastic iritis that had lasted two months, and he had had all the accepted methods of treatment. His condition cleared up rapidly with the treatment outlined for highly acid stools.

COMMENT

By far the largest number of cases of choroiditis, retinitis, iridocyclitis, glaucoma and the like I have diagnosed as to the condition present, but I cannot go any further in the etiology or in the treatment. The cases run their course in spite of the treatment adopted. It would be the ideal condition if we could take such cases and study them extensively so as to arrive at the cause. The reference of eye infections to the intestinal tract is not new, as evidenced by the article of such writers as Herter and Smith, published in 1894, describing their cases of ophthalmoplegia, low grade conjunctivitis, etc., which were cured by treatment of the intestinal tract. My attention was called to this article by Dr. Coffin, who was incidentally the means of directing my attention to the intestinal tract.

I do not claim that my work is new. It is simply an experiment. But the results in the series of sixty-seven cases I have treated were in the main very striking, and it seemed well worth while to work along these lines.

ABSTRACT OF DISCUSSION

Dr. Edgar S. Thomson, New York: Focal infection of the eye attracts attention most frequently in connection with uveal disease. Its intractability and tendency to relapse are well known. Cases of iritis and cyclitis relapse in spite of the greatest care and the most careful control. The baneful influence of the digestive tract, especially the intestinal tract, has long been recognized, and treatment has often been productive of good results, but the question has not been placed on an exact basis. The exact method mentioned by the essayist has not been employed. Intestinal vaccines have been used, and cultures of acid-producing bacilli have been given, chiefly by mouth, but with no very exact checking up of results, at least in ophthalmic work. Judging by clinical experience, the most important single factor in the examination of the feces is the determination of the reaction. A low acid reaction is the most desirable balance for reducing putrefaction and for establishing the cultures of colon bacilli, and, given these two factors, the fermentative processes remain more stable and the local condition in the eye does not recur. In our cases the local symptoms in the eye apparently have kept pace with the intestinal condition. Manifestly toxic conditions—iritis, cyclitis and choroiditis—have improved rapidly, and in the majority of cases have not relapsed in the time during which we used the method. The course of the disease has in general been much shortened and local absorption of precipitates and exudates has gone on in a way that was suggestive of a "cut-off" in the toxin supply. A few cases of optic neuritis and episcleritis have been affected very favorably. Certain forms of keratitis, associated with slow tissue repair, and low hemoglobin percentage, have done remarkably well. A few cases of intractable ciliary cramp have been affected very favoraby.

Dr. Hiram Woods, Baltimore: There is no doubt that there is a sufficiently intimate association between gastro-intestinal disorders and these intractable cases of uveitis and recurrent ciliary cramp to justify the suspicion of cause and effect. Those of us who have had clinical experience in studying these cases can appreciate the value of Dr. Dwyer's paper, provided the claim is confirmed. He brings us down to two very definite things, which we ought to get clearly in our minds, the hyperacidity on the one hand, and the hyper-alkalinity on the other hand, plus the absence of the colon bacillus. If these are definite diagnostic points, we have something far more reliable to go on than we have ever had before.

Major Harry S. Gradle, Chicago: I believe that absorption from the intestinal tract, as Dr. Dwyer said, plays a far greater rôle in the etiology of various ocular diseases than we have been willing to acknowledge for some time. We are dealing with an absorption of toxins from the intestinal tract, which affects an organ unable to withstand the influence of these toxins. Toxins in the intestines normally result from the breaking down of the various protein constituents of the food. There are few types of absorption, the abnormal absorption of normal toxins, and the absorption of abnormal toxins. By that I mean, in the first case, the excessive production and absorption of toxins from the intestinal tract, more than it is accustomed to (usually the result of a more or less chronic constipation); and, second, distubrances in metabolism, resulting in the production of abnormal toxins, that the human system is not at all accustomed to, and has no power of protecting itself against. The cases require radically different treatment. We must establish a normal passage through the intestines and eliminate the hyperproduction of the so-called normal toxins, and we must correct the disturbance of metabolism that results in the production of the abnormal toxins.

Dr. Clark W. Hawley, Chicago: The analysis of feces is important. I have been advocating the study of the relation of uveal tract disease and the toxins from the lower bowel for a number of years. My first discovery of a relation between uveal tract disease and toxins from the lower bowel was in my own case. I was suffering from a slowly increasing chronic cyclitis of both eyes and supposed I was getting blind, or nearly so. I was treating an autointoxication following a very severe case of facial erysipelas and soon discovered that my eyes were improving. This led me to believe that there might be a relationship between the two. Since then many cases have been treated along the same lines with as good results. I have been surprised at the number of cases of inflammatory glaucoma which were due to these toxins. Six patients treated remain cured.

Major Walter B. Lancaster, Boston: I was surprised that the writer in enumerating the foci of infection outside the intestines limited himself to the teeth and tonsils. There are many other foci of infection which affect the eye secondarily. I have been very slow to accept the theory that these ocular inflammations arise from the intestines. I have inclined toward the theory that the ocular condition is of bacterial origin, the micro-organisms gaining access through the blood stream. This was well illustrated in one case in which the seminal vesicles acted as an infection focus.

Dr. Will Walter, Chicago: There is no authority for the thought that the colon bacillus is infecting the intestinal tract in these cases, and it must not be forgotten that the liver intervenes between the absorbed intestinal contents and the general circulation. A focal infection means a tissue infection the chemic or bacteriologic elements of which are carried by the blood stream to areas more or less remote, where they set up inflammatory changes. Patients suffering from intestinal toxemia often show little indican or none. Whether there is present in these cases another toxin than that included in the indoxyl sulphates, and hence not shown by the tests for indican; or where there are elements which alter the tests in these cases; or whether, as I think most probable, the hepatic functions are neutralizing or altering these toxins, is not clear.

Dr. James G. Dwyer, New York: The term "infection" does not mean the presence of bacteria in the blood. Bacteria produce protein toxins, and we have the phenomenon of anaphylaxis. We can produce the anaphylactic phenomenon in the body by simple extraction from bacteria, whether they are pathogenic or not. With regard to the liver: Work has been done showing that the extracts of spleen, of heart, of lung, etc., are nontoxic, but there is a toxic quality in the liver, because it takes up these toxins. It does not matter whether the toxin comes from putrefactive organisms. We are not dealing with infections from the colon bacillus. That is exactly the opposite of what I am trying to bring out. The three common foci are usually the teeth, the tonsils and the intestinal tract. I do not know that we are far enough advanced to identify what are normal protein products and what are abnormal. The point I wish to bring out is this, that the reason the joints and the eyes are affected is in all probability because we have a very sudden change from blood supply to lymph supply. In the uveal tract we have an ideal condition of lymphatic supply.

EARLY DIAGNOSIS OF CEREBROSPINAL MENINGITIS BY THE EXAMINATION OF STAINED BLOOD FILMS

REPORT OF A CASE *

W. W. KING, M.D.
Surgeon, U. S. Public Health Service
SAN JUAN, P. R.

According to the clinical notes furnished me by Dr. N. Doval of San Juan, Porto, Rico, the attending physician, A. B., a mulatto girl, aged 4½ years, native and resident of San Juan, who had never had any serious illness, and whose family history was unimportant, after a slight rhinitis lasting several days, without fever or any particular discomfort, complained of headache and severe pain in the right shoulder. This was about 6 p. m. Later she was noticed to have high fever. When first seen by Dr. Doval, at 8 o'clock, the temperature was 39.8 C. (103.6 F.); pulse, 130, and respiration, 28. She had vomited several times. About midnight, convulsions began and continued several hours; there were clonic spasms of short duration. The temperature was 40.2 C. (104.4 F.), the pulse weak and uncountable. The patient vomited a dark colored fluid.

I first saw the patient at 8 a. m. She was then in coma; the extremities were cold; there was no pulse. On the cheeks, arms and body were several irregular and indefinite areas slightly darker than the normally dark skin. Supposing this to be a beginning hemorrhagic eruption (later confirmed), I made a tentative diagnosis of cerebrospinal meningitis. Two small drops of blood were squeezed from a puncture in the lobe of the ear, but the peripheral circulation had so nearly stopped that no more could be obtained. These were used for making two smears on slides. A syringe for making lumbar puncture was not at hand, and the patient died before the laboratory assistant sent to do the lumbar puncture arrived at the house.

Death occurred at 9 a. m., about fifteen hours after onset.

At the laboratory, a slide was immediately stained with Leishman's stain. The enormous number of leukocytes attracted attention at once, and then it was seen that some of the polymorphonuclear neutrophils contained a diplococcus resembling the meningococcus. The second slide was stained by the Gram method controlled by the simultaneous staining of a known gram-positive coccus, and the diplococci were seen to be gram-negative. On these points, the diagnosis of cerebrospinal meningitis was regarded as confirmed.

Necropsy was refused, but permission was finally given to make punctures to obtain blood, and to make a small opening into the spinal canal. This was done five hours after death, and 15 or 20 c.c. of blood were secured from the right heart, basilar meninges and dorsal region of the spinal canal, all

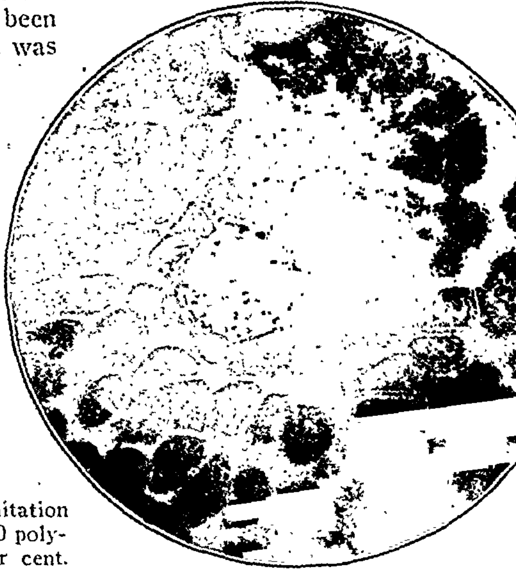
* From the laboratory of the Institute of Tropical Medicine and Hygiene of Porto Rico.

of which were filled with dark fluid blood. Lumbar puncture failed to obtain blood or fluid, although the point of the needle seemed to be free in the cavity. A large number of cultures were made in ascitic bouillon, and on ascitic agar and blood-serum agar, and many smears also were made from each sample of blood. All cultures remained sterile, and prolonged search of the stained slides failed to show a single diplococcus. The meninges, as seen through a small opening in the dorsal region, appeared intensely injected without signs of any exudate. After death, the areas of darker skin were clearly hemorrhagic and more numerous than in life. In size they varied from mere points to several centimeters in diameter.

The diagnosis in this case was particularly important because the case occurred in a populous part of the city, and the rapidity with which death took place attracted considerable notice and alarm. It occurred at the time (November, 1916) when public apprehension had been much aroused by the epidemic of poliomyelitis in New York, a port with which San Juan has frequent steamer connections. The outbreak of bubonic plague in Porto Rico in 1912 was by no means forgotten. Rapidly fatal malaria occurs in the island, though fortunately it is rare, and the child, so far as known, had not been in a malarious district. That it was true typhus fever was less likely, as this is a rare disease in warm countries, and never reported in Porto Rico, yet it seems possible that it might occur. Hemorrhagic smallpox was not improbable in view of the prevalence of smallpox during the previous year. Cerebrospinal meningitis in sporadic cases is occasionally seen.



Meningococcus in blood film, within neutrophil.

There seems little doubt that the diplococcus seen in the blood films was the meningococcus. It was characteristic in size, morphology and staining reaction, and in its limitation within the cells. In a count of 1,000 polymorphonuclear neutrophils, 3.7 per cent. showed the diplococcus, sometimes only one or two pairs but generally in fair quantity; not infrequently the cell was thickly crowded with them. The photomicrograph was taken from an average specimen. No extracellular organisms were seen.

Sufficient blood could not be obtained to make a total count of the leukocytes, but their great abundance in the stained specimen indicated a very high leukocytosis. The differential count of 500 leukocytes revealed: polymorphonuclear neutrophils, 62.0; small lymphocytes, 6.4; large lymphocytes, 2.8; large mononuclears, 24.0; transitionals, 4.0; eosinophils, 0.8; basophils, 0. The Arneth formula was: Class I, 43; Class II, 33; Class III, 20; Class IV, 4; Class V, 0; index (Arneth), 76; (Bushnell and Treuholz) 86, a considerable shift to the left. It must be remembered that this blood was taken during the last hour of life when the circulation had become very sluggish, and it is probable that the blood picture shown was not that of a few hours earlier. It is given as noted, but it is of comparatively little importance beside the fact of the presence of the meningococcus, which made accurate diagnosis possible.

It is now generally accepted that the meningococcus passes to the blood from the mucous membrane of the nasopharynx and produces a primary blood infection to which the meningitis is secondary. This view has been emphasized recently by Herrick,[1] Medlar[2] and Thomsen and Wulff,[3] but they apparently did not utilize this "meningococcus sepsis" or bacteremia for early and rapid diagnosis by search for the diplococcus in stained blood films. Thomsen and Wulff used blood cultures and concluded that the number of meningococci in the blood may not be very large, and that they may not remain long in the blood stream. Elser[4] had previously expressed the same opinion.

Some months after seeing the foregoing case, I had the opportunity of looking over the literature of meningitis at the Surgeon-General's Library in Washington, D. C., and I found but one reference to the use of blood films for diagnosis in this disease. Horder,[5] in speaking of the diagnosis with reference to "superacute" cases, says that the examination of blood films may prove the nature of the case; presumably by finding the meningococcus. That this method has not been used more is due apparently to the belief that the organisms are too few in number in the blood stream for ready demonstration, and this belief seems based on the comparatively few colonies or negative findings after cultures have been made of considerable quantities of blood.

The presence of so many meningococci in the films from this case shows that they may be numerous in the peripheral circulation, and suggests that in other cases they may be in sufficient number for diagnostic purposes. It also brings up the possibility that cultures may give an erroneous impression as to the number present in this situation. Aside from the technical difficulties of making cultures of the meningococcus, there may be other reasons why cultural results may not be a true index to the number of meningococci in the circulating blood. The antimeningococcic serum produced by the response of the system to the infection is bacteriolytic, opsonic and antitoxic (Frost[6]), and its opsonic action is so promptly manifested that the meningococcus is found characteristically within the cells (phagocytes). Phagocytosis being a step toward the destruction of the invader, a phagocyted organism suffers a reduction of vitality, probably to such an extent that it quickly becomes incapable of reproduction, particularly under the artificial conditions of culture. This may be especially true of the meningococcus, which is very susceptible to unfavorable influences, and, if so, then successful culture must come from the more vigorous extracellular individuals. If there is a marked degree of phagocytic activity, these extracellular forms may be few or absent, giving poor results in culture, while the intracellular, that is, phagocyted forms, may yet be sufficiently numerous to be demonstrable in smears. Furthermore, the antimeningococcic serum present in the blood used for culture may exert enough inhibitory action to prevent the development of some organisms. It is interesting to note that Elser reported a fatal termination in 80 per cent. of the cases in which the meningococci were obtained by culture, an observation which is consistent with the foregoing ideas, the insufficient production of antimeningococcic serum permitting the persistence of extracellular forms in the blood stream.

Whatever may be the sequence of events ordinarily taking place in the blood early in an attack of meningitis, the fact remains that in this instance the meningococci were easily found in the blood and were of great practical use for diagnosis. If the case was exceptional in this respect, it is interesting as an exception. It is not reported as an evidence of meningococcic bacteremia, for that has already been well established, but as an instance in which the bacteremia was utilized for making an early and rapid diagnosis. The thought is suggested that this method may have greater diagnostic possibilities than has been supposed. There are few diseases in which early diagnosis is so important, especially in very acute cases, and if the method is at all useful, it is applicable during the first hours or day, and in those cases that do not progress beyond the bacteremic stage. It is not thought that it would supersede lumbar puncture, but that it may have a place and value of its own, not only for the early information that it may give, but also on account of the ease and rapidity with which it may be carried out. The procedure requires only a minimum of apparatus and skill, and the taking of a few drops of blood from the lobe of the ear can often be done in cases in which the lack of a syringe, family opposition, or other circumstances render the more formidable operation of lumbar puncture difficult or impossible. In the examination of the films, the brilliantly stained diplococci are so readily seen that a large number of slides can be rapidly examined.

To determine its diagnostic value and limitations, it will be necessary to ascertain certain facts, such as: 1. The frequency with which the meningococcus may be so found. 2. The number of slides necessary to examine before a negative result can be announced, that, is, the quantity of blood required. 3. Whether it is in the very severe or fulminating cases only that it may be found; if longer search may not show it in the milder cases also. 4. If not demonstrable practically in the milder cases, in what degree of severity it may be expected. If limited to only certain very severe cases, it would still be very valuable, as it is precisely in such cases that prompt diagnosis is most desired. 5. In those cases in which it may be encountered, how early and how late this may be possible.

I could not find any reports of work having been done along these lines, yet the subject seems worthy of investigation. It would require the systematic study of many films from many cases of meningitis of different degrees of severity, controlled by clinical and other bacteriologic evidence, and I regret that I have not the opportunities for doing it.

A SELECTIVE MEDIUM FOR B. INFLUENZAE

OLEATE-HEMOGLOBIN AGAR *

O. T. AVERY, M.D.
Captain, M. C., U. S. Army
NEW YORK

The reports of various observers indicate that great difference of opinion exists concerning the etiologic significance of *B. influenzae* in the present epidemic of influenza. Some investigators have been able to isolate this organism from a large percentage of the cases that they have observed; others have succeeded in recovering it in very few instances. It is possible that technical difficulties in the isolation and growth of this microorganism may be in part responsible for the discordant results obtained in different laboratories. In any case, all those who have had experience in the isolation and cultivation of *B. influenzae* agree that in working with this organism, there are a considerable number of technical difficulties that have been only partly overcome by the methods so far devised.

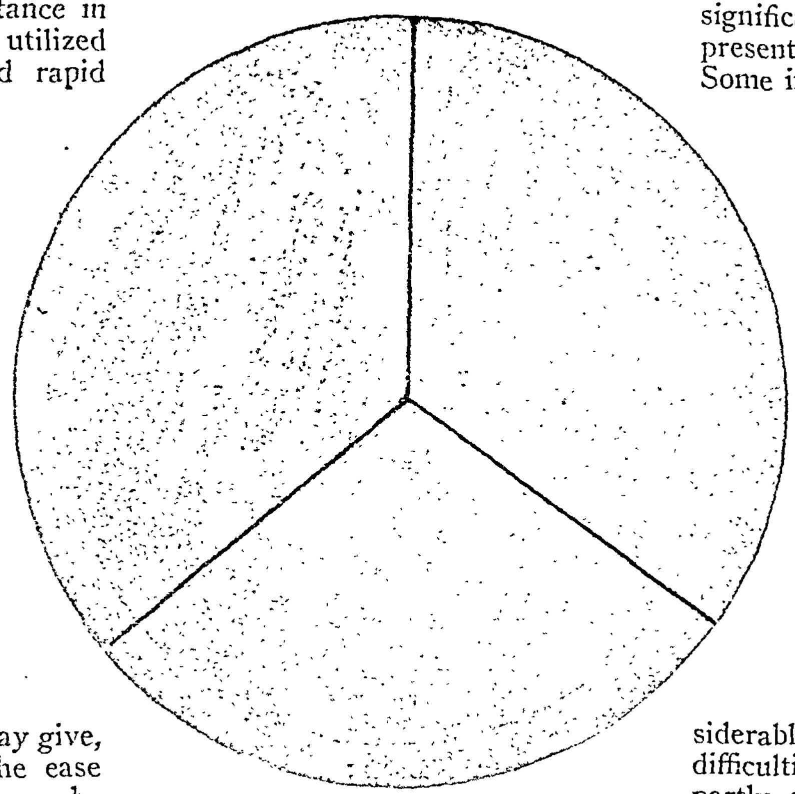

Fig. 1.—Plain blood agar plate: Lateral sectors show growth of pneumococcus and Streptococcus hemolyticus, lower sector B. influenzae, growth present but not visible in photograph.

In obtaining the organism from the sputum or throat cultures, or even from cultures made at necropsy, it is usually found in association with many other bacteria, most of which grow with greater luxuriance than does the influenza bacillus. It is evident, therefore, that if a medium could be devised that would prevent the growth of at least certain of these other organisms, such a medium would be of great assistance, especially if at the same time the growth of the influenza bacillus could be enhanced.

An attempt has been made to develop such a medium, and in the present report the results so far obtained are briefly described. In the development of this medium, use has been made of the observation that soaps of the unsaturated fatty acids are bactericidal for certain bacteria. In preliminary studies it has been found that the addition of sodium oleate to mediums prevents the growth of certain gram-positive organisms, principally pneumococcus and streptococcus, while the growth of *B. influenzae* is enhanced by the presence of this substance. The oleate-hemoglobin medium, therefore, was devised and has proved very satisfactory for the isolation of this organism.

---

* From the Hospital of the Rockefeller Institute.

PREPARATION OF THE MEDIUM

Meat infusion agar (2 per cent.), which is neutral or slightly alkaline in reaction, is used as a base. To this is added a solution of sodium oleate sufficient to make a final concentration of 1:1,000. A serum-free suspension of red blood cells in broth is freshly prepared from sterile defibrinated rabbit's blood. One c.c. of this corpuscular suspension is added to each hundred c.c. of oleate agar, the addition of blood being made while the medium is still hot. Plates are then poured containing about 15 c.c. each of oleate-hemoglobin agar and used fresh to avoid drying out of the medium.

In the preparation of oleate-hemoglobin agar attention should be given to certain details:

1. *Agar.*—Two per cent. meat infusion agar having a reaction of from 0.3 to 0.5 acid to phenolphthalein should be used. The initial hydrogen ion concentration of the agar should represent a p_H of from 7.3 to 7.5. Hormone agar prepared according to the formula of Huntoon[1] yields excellent results, and has been used in the present study.

2. *Sodium Oleate.*—Two per cent. solution of sodium oleate (neutral) is made in distilled water, sterilized in the autoclave and kept as a stock solution. Five c.c. of this 2 per cent. solution of oleate is added to 95 c.c. of agar, giving a concentration of 1:1,000. In the present work Kahlbaum's sodium oleate has been used, but other preparations are serviceable.

3. *Suspension of Red Blood Corpuscles.*—Sterile defibrinated rabbit's or human blood may be used. Since serum is known to inhibit the action of oleate, and since hemoglobin is the constituent of blood essential for growth of *B. influenzae*, a serum-free suspension of the red corpuscles is used instead of whole blood. The red cells are removed from the defibrinated blood by centrifugation, the supernatant serum is pipetted off, and the corpuscles are made up to the original volume of blood by the addition of broth. One c.c. of this suspension of red cells is added to each hundred c.c. of oleate agar. The suspension of blood corpuscles should be added directly while the medium is hot, and just before use.

4. *Formula.*—This calls for:

Agar	94 c.c.
2 *per cent.* solution of sodium oleate	5 c.c.
Suspension of red blood cells	1 c.c.

Oleate-hemoglobin bouillon may be prepared in the same way by substituting broth in the place of agar in the foregoing formula.

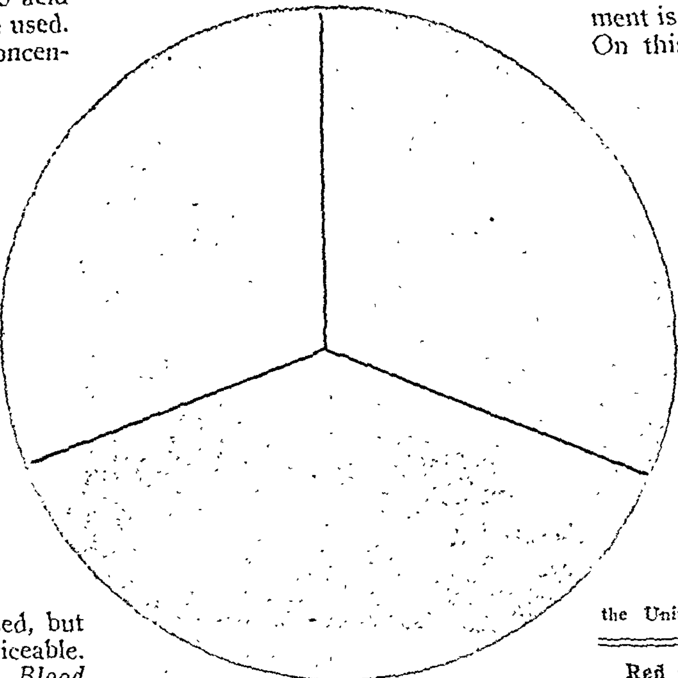

Fig. 2.—Oleate-hemoglobin agar plate: Corresponding sectors are planted with same organisms as in Figure 1 and show enhanced growth of B. influenzae in lower sector and complete inhibition of growth of pneumococcus and Streptococcus hemolyticus.

Cultures taken from the nasopharynx by the West tube or from the throat by direct swabbing should be streaked on the surface of the oleate-hemoglobin medium according to the technic described for the detection of meningococcus carriers.[2] Similar plates should also be made from the sputum. At necropsy, cultures should be taken from scrapings of the tracheal and bronchial mucosa, as well as from the lung exudate.

All culture plates should be incubated for forty-eight hours at 37 C.

COMMENT

The use of this medium has led to an increase in the percentage of positive findings of *B. influenzae* in actual cases of the disease and in convalescents. A report of these studies will be made in a subsequent communication.

Because of more luxuriant growth on oleate-hemoglobin medium, the colony of *B. influenzae* appears larger and less translucent than on ordinary blood agar, and in a later stage of development is not infrequently nucleated. On this medium, the gram-negative cocci of the *M. catarrhalis* group, staphylococci and occasionally diphtheroid bacilli grow, while pneumococci and streptococci of the hemolytic and *S. viridans* variety fail to develop.

The use in culture mediums of soaps of the unsaturated fatty acids, of which sodium oleate is a representative, suggests the application of this principle in bacteriologic studies of other organisms.

Red Cross Work Under Difficulties.—Dr. W. S. Dodd of the American Red Cross, working at Mejdel, near Jerusalem, Palestine, reports to headquarters in Washington, D. C., on conditions in the hospital in which he was stationed. The hospital was made up of about twenty-five tents, with a dispensary tent, living quarters for the staff, etc. It was located on a sandy district with thistles and scant grass, and it was the custom of every one, including the staff, to go barefoot. The patients in the clinics numbered from sixty to 100 a day. Of 252 operations performed by Dr. Dodd in less than seven weeks, 222 were for eye troubles, of which trachoma cases formed the great majority. Dr. Dodd treated a number of patients with bombed hands, of which there were many in the earlier days. The cases he treated were mostly in children who picked up unexploded Turkish bombs which had been laying in the fields from the time of the British advance in the Gaza region. Many fingers and hands were lost from this cause. Lice, fleas and other vermin were everywhere, and maggots were frequently found in wounds, as the favorite dressing of the natives, a piece of raw meat, is a good breeding place. They were found in the ears, and in scalp and other wounds. Difficulty was experienced in making the patients conform to sanitary requirements, and penalties had to be imposed for violations.

NEPHROLITHIASIS PURPURA HEMORRHAGICA AND STREPTOCOCCUS INFECTION

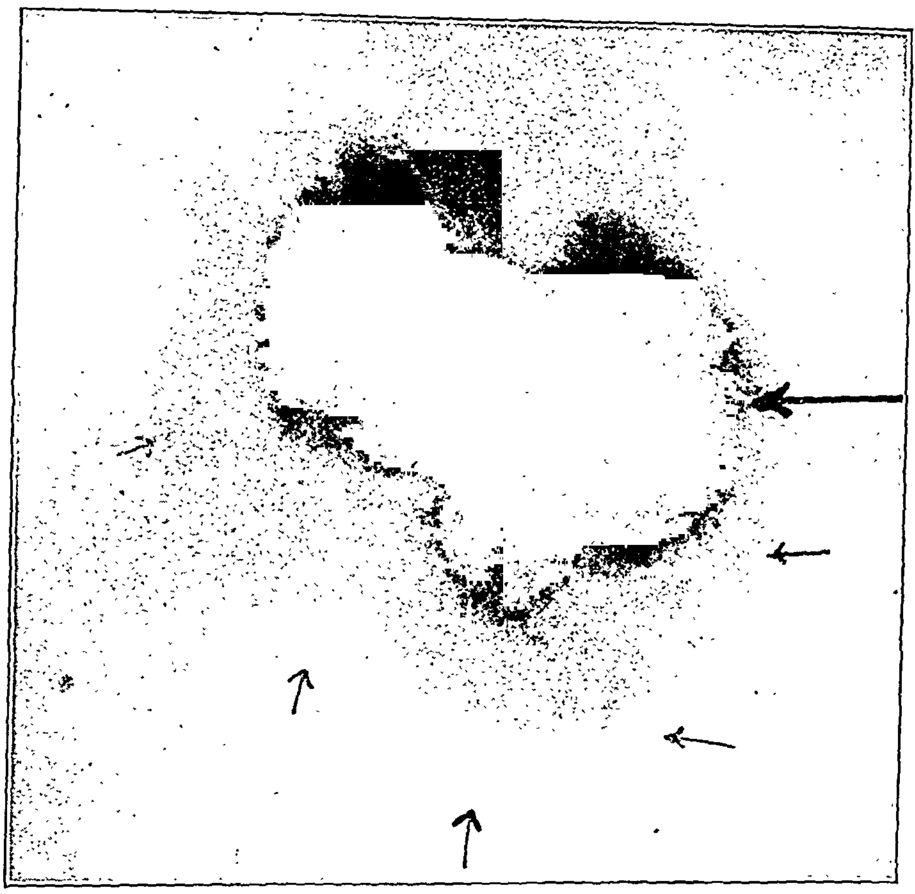
REPORT OF A CASE WITHOUT FEBRILE REACTION *

AUGUSTUS B. WADSWORTH, M.D.
ALBANY, N. Y.

I record the observations in this case on account of their clinical interest rather than any complete scientific study of the problems concerned, as these are too subtle to be solved by clinical methods. The history is therefore abstracted in order to bring out the salient points.

REPORT OF CASE

A woman, aged 59, consulted Dr. George W. Endicott of Plainfield, N. J., on account of bloody urine. She complained of no other symptoms. She was referred to me for diagnosis. In the urine, considerable quantities of blood, numerous pus cells containing bacteria, but no casts were found. A specific gravity of 1.015 and the quantity of urea, estimated, 1.1 per cent., or 17.8 gm., in twenty-four hours, was considered practically normal for a woman of her age, passing more than 1,600 c.c. of urine a day. The urine was not offensive and no tubercle bacilli were present. Bacterial cultivation under aerobic conditions on the surface of agar was sterile, but a streptococcus was finally cultivated under these conditions after it had been isolated under anaerobic conditions. These streptococci were present in large numbers and in pure culture in urine obtained under aseptic precautions directly from the bladder. In the examination of the blood, 9,500 leukocytes were found.



Roentgenogram of right kidney showing calculus (indicated by large arrow) and lower margin of kidney (indicated by small arrows). The roentgenogram was taken by Dr. Lewis Cole, New York.

Although the patient had no febrile reaction, complained of no symptoms of pain or the like, and had no discomfort save the annoyance from increased frequency of micturition, it was evident that there was a well-marked streptococcus[1] infection at some point of the urinary tract—either the bladder, ureter or kidneys.

Treatment of the bladder by irrigation, first with argyrol and later with permanganate solutions which were increased in strength to the limit of tolerance, failed to produce any material change in the situation. An examination by roentgen ray was accordingly resorted to in order to determine the presence of a focus of infection higher up, and as a result of this the presence of an enormous calculus involving practically the entire right kidney was discovered, thereby establishing the diagnosis.

In the course of these examinations and treatment, the patient developed marked symptoms of purpura hemorrhagica dating from the time I first saw her, when she called my attention to vibices produced by the least injury. This condition increased. Vibices developed after scratching, and areas of purpura as large as the palm of the hand and even larger followed injuries that could not even be recalled. No cardiac lesions or arteriosclerosis were found on physical examination. The blood pressure was not above 150 mm. of mercury.

It was thought that the conditions in this case were extremely delicately balanced, and of clinical interest. A calculus had evidently developed insidiously and involved the entire kidney without giving rise to any symptoms or discomfort. Although the patient had complained of a "weak bladder" and had also been treated for cystitis in the course of which one of her physicians had instructed her in the use of the catheter, there is no point in the history of the case that would indicate the beginning of a streptococcus infection. Although married, the patient had never borne children. The relationship of the calcalus to the infectious process in the kidney is thus obscure.

In order to treat this case, a surgical operation was considered necessary to remove the calculus; and in order to safeguard the patient against possible extension of the streptococcus infection at the site of operation, streptococcus vaccines were administered. These were prepared from the autogenous strain as follows:

Streptococci taken from the surface of agar cultures were suspended in salt solution and killed by an hour's exposure at 55 C. Culture filtrates were prepared from the streptococcus growth in human blood serum broth after three weeks' incubation by infiltration through a Berkefeld filter and heating at 53 C. for an hour.

The effect of these two different vaccines was studied very closely in the treatment of this case. The culture filtrates were first used. A cubic centimeter was inoculated, and within twenty-four hours a marked local reaction with extensive purpura at the site of inoculation developed. The area of the reaction was approximately the size of the palm of the hand. A second inoculation in the other arm the next day was followed by a similar but less marked result. The third inoculation was made with the vaccine of bacterial cells from agar in the first arm inoculated. The reaction following this was slight and not accompanied with marked purpura. From that time on the two treatments with vaccines alternated with filtrates of the human blood serum broth culture and the vaccines of the streptococcus cell in increasing doses in each instance. As a result of this treatment it was possible to compare the local effect of the two forms of inoculation which seemed to differ so materially. The bacterial cells never gave rise to reactions of the type produced by the culture filtrates which so closely resembled the typical purpura

---

* Read before the American Society for the Advancement of Clinical Investigation, May 11, 1914.

[1] The morphologic and cultural characters of this streptococcus were not unusual in any particular. Capsules were not demonstrable. It was very slightly hemolytic in blood agar, developing greenish colonies. Five c.c. inoculated in rabbits failed to kill the animals, but streptococci from fatal human infections often fail to kill animals.

hemorrhagica that developed spontaneously as the result of injury. Furthermore, during this treatment with these vaccines the occurrence of spontaneous purpura took place with less frequency until finally it disappeared after about three weeks' treatment, and the patient has been free from it ever since.

Following this treatment the patient was referred to Dr. Endicott for surgical treatment. He successfully removed the right kidney, and the operation was followed by a complete recovery.

COMMENT

The case is thus of interest on account of the large size of the stone, its insidious development, and the presence of a streptococcus infection associated with it, doubtless for an indeterminate number of years, without giving rise to febrile reaction or any significant symptom complex save that of purpura hemorrhagica, which might reasonably be attributed to the liberation of toxic substances under conditions of disturbed balance in the protective mechanism of the body tissues. With immunization, the efficiency of the protective mechanism was gradually but completely restored. The culture filtrates used as vaccine proved more active than the vaccines prepared from the bacterial cells.

It is also of interest to note the difficulty of securing cultures by the usual methods of bacterial examination and the necessity of resorting to anaerobic cultivation for this purpose.

The significance of a single clinical observation which admits of no precise interpretation such as is possible in experimental study is extremely limited, but it is certainly suggestive, and it may be possible to determine more accurately the conditions underlying the development of these reactions of purpura when similar conditions can be induced in animals. There is, however, always a break in the analogy between the result of experiments on animals and the phenomena of disease as it occurs in man; hence the importance of this record — an experiment conducted on man.

CITRATED BLOOD IN TREATMENT OF THE PNEUMONIA FOLLOWING INFLUENZA *

RESULTS OF THE USE OF BLOOD FROM CONVALESCENT INFLUENZA PATIENTS

W. W. G. MACLACHLAN, M.D.
Assistant Professor of Medicine, University of Pittsburgh School of Medicine

AND

W. J. FETTER, M.D.
PITTSBURGH

The early days of the epidemic with its fatal and clinically somewhat atypical pneumonia are far from pleasant memories. Any measure, therefore, that gave us a better chance to combat this infection was most opportune. McGuire and Redden[1] treated thirty-seven pneumonia patients with thirty recoveries, six still under treatment and one death, by using the blood serum intravenously, taken from influenza patients that had recovered. They used from 300 to 700 c.c., as was indicated. This meant, of course, that large amounts of blood had to be taken from the donors, up to 800 c.c. of blood being withdrawn from one individual. They noticed that the serum appeared to vary in the amount of immune substance that it was supposed to contain. In fact, ten out of seventy serums clinically failed to demonstrate any evidence of this. Brown and Sweet[2] referred to the use of citrated blood in two cases of influenzal pneumonia with recovery in each case. They gave 90 and 120 c.c., respectively.

The epidemic from the point of view of the medical service at the Mercy Hospital, Pittsburgh, began about Oct. 10, 1918, when we received almost a score of soldiers from the University of Pittsburgh as our first instalment. About three days later the pneumonia commenced, and at the first of the epidemic, as has been observed elsewhere, it was particularly severe. We employed arsphenamin in two pneumonia cases, but there was no evidence that it had any special effect in the clinical course of the disease. One of these patients recovered, with, we feel sure, no thanks to the arsphenamin; the other died about seventy-two hours after the administration of the arsphenamin from the pneumonia. October 17, we began treating our patients with citrated blood taken from persons who had recovered from an attack of influenza.

We chose the citrated blood method as it appeared to us to be more convenient, and further, that possibly one would not need to remove so much blood as would be necessary in order to collect serum in considerable quantities. One must admit that 800 c.c. of blood taken from one just recovering from an acute illness seems to be a considerable amount, but apparently it was followed by no ill effects.

Our technic is simple. It is necessary to have two 50 c.c. Lüer syringes, two 250 c.c. Ehrlenmeyer flasks, one short rubber tube with a fairly large needle attached for taking the blood, and a rubber tubing apparatus which we have used here for giving arsphenamin. This consists of two small rubber tubes, a long and a short one, joined by a triple cock, by which the flow of a solution can be introduced one way or the other. A metal attachment is fitted to the Lüer syringe, and the needle is attached to the short tube. The long rubber tube is placed in the Ehrlenmeyer flask, containing physiologic sodium chlorid (0.9 per cent.) solution, and a small quantity (20 c.c.) is drawn into the syringe. The sodium chlorid solution is first given to make sure that the needle is properly placed in the vein. The rubber tube is then transferred to the flask containing the blood solution (40 c.c. of 2 per cent. sodium citrate in physiologic sodium chlorid solution to from 75 to 100 c.c. of blood), which is slowly injected into the vein.

It is essential to carry out a Wassermann test on each donor. We had no positive reactions among our donors, who were practically all students from the Army Training Corps. Toward the end of the epidemic, when most of the soldiers had gone and donors had become very scarce, some civilian ward cases were tested for use. Strangely enough, half showed positive Wassermann reactions, a point probably well to remember if work of this type is to be applied to civil life.

The matching of blood, iso-agglutination reaction, was studied in the first two cases; but after that, simply on account of the fact that time and assistants were limited, it was not continued. We observed no evidence of any ill effect from our neglect of this procedure. There was no hematuria in the patients

---

* From the Mercy Hospital.

[2] Brown, W. L., and Sweet, B. L.: Treatment of Influenzal Pneumonia by Citrated Transfusions, The Journal A. M. A., Nov. 9, 1918, p. 1602.

injected. We thought that the amount, never more than 100 c.c. at one time, was probably not conducive to produce ill results. Certainly, if possible, it is better to carry out this agglutination work.

We injected as a rule about 75 c.c. of blood. Four injections were the most we gave to any one patient. We were unable in the first two weeks to inject more than once in twenty-four hours, for no other reason than the lack of time. We think that in all probability a few cases were lost on this account. Latterly, the pneumonia cases seemed to be of a somewhat milder type and reacted more readily. In all we have taken about 100 specimens of blood from donors and have given ninety-three injections to pneumonia patients.

The number of patients treated in the course of a little more than three weeks was fifty-four. They represented entirely the severe influenzal infections—all had pneumonia. The milder types of influenza were very carefully conserved to be held as donors, as we made it a rule not to use the blood from any patient in whom the disease had not come to normal of its own accord. Thirty-four patients recovered and twenty died. It would be well, however, to say that in this twenty there were seven patients that were in the very termination of the pneumonia, showing unmistakable evidence of edema of the lungs. Cases as late as these can in no way be used as an index of the value of any type of treatment. Death occurred in all of the seven within twelve hours after the injection. The accompanying table gives really a more accurate statement of our results. The mortality was 27 per cent.

From the table one can readily see that the earlier the case was treated the better was the chance for recovery. In view of the fact also that the blood given probably had an effect only on the influenzal side of the infection and not against the prevalent secondary invader, the pneumococcus, it is only to be expected that the late cases would show poorer results. It is also to be kept in mind, as Christian[3] has shown, that the presence of pneumonia is a much more difficult problem to solve than the same condition in our ordinary pneumococcus infection of the lung. Undoubtedly, in many of the prolonged influenzal cases with only râles at the bases, particularly at the apexes of the lower lobes, bronchopneumonia was present. When we use the term pneumonia we refer, however, only to those that demonstrated signs of consolidation in the usual sense. We know certainly that some of the cases in the table were of longer duration than is indicated, although by physical signs that was the apparent time.

RESULTS OF TREATMENT BY THE CITRATED BLOOD METHOD

Day of Pneumonia	Recovered		Died
First	18		2
Second	9		6
Third	4	(1 empyema)	1
Fourth	3		4
	34		13

The reaction of the patient effected by the blood transfusion was really about the same as that seen in the use of antipneumococcic serum in lobar pneumonia. The more striking results were observed in those cases in which treatment had been given in the early stages of the pneumonia. At times one injection (from 75 to 100 c.c.) produced a crisis. In most of these cases it took from twenty-four to thirty-six hours to reach the crisis. Lysis was encountered more frequently in those in whom the pneumonic process was of longer duration. In these also, two or more injections were frequently necessary. At times, after the second injection, an almost typical crisis was observed. In a certain percentage of the patients that recovered, almost one quarter of them, a mild, febrile reaction (from 99 to 100 F.) from one to three days was noted after the case had come to normal. Absorption from focal areas in the lung during their resolution is the most likely explanation of this temperature elevation. We noticed a fall in temperature, following almost every injection given. In fact, we had only one case in which there was no change in this regard. We considered that in all probability we were dealing with a pure pneumococcic infection, secondary to the influenza, and hence no impression was made on the condition. A case similar to this one that had reacted in a like manner after two blood transfusions dropped by lysis after 50 c.c. of antipneumococcic serum were used.

A certain percentage of the transfusions, usually the first, produced a chill with a temporary rise in temperature and a subsequent fall. In seven patients the chills were sharp, lasting from ten to fifteen minutes. About an equal number (six) felt a little chilly, but had not a definite chill. There was no relation, whatever, between the chills and the mortality. Serum or blood subcutaneously (from 0.5 to 1 c.c.) would probably lessen this rather disagreeable after-effect, in the way suggested by Cole in the use of the antipneumococcic serum.

There is one other point to be watched. In those patients who were rather dyspneic or cyanotic or who had respiratory discomfort, as from pleural pain, the injection had to be given very slowly; otherwise these symptoms were temporarily increased.

The temperature reaction, however, should not be taken as the whole guide. As a rule, it corresponded to the condition of the patient. As the pulse rate in practically all of our pneumonic cases was of the relatively slow type (from 80 to 100), but little information was to be received from this source as to the change in the patient. The general appearance and comfort of the patient was noticeably improved in those cases reacting favorably. From the physical signs, we have seen a dry, consolidated area, in the course of twelve hours after an injection, present all the signs of a lung in resolution.

During the height of the epidemic when we had more than 100 soldiers in the wards at one time, the problem of obtaining donors was a very simple one. There were always cases in the convalescent stages. Toward the end of the epidemic, however, the donor problem became somewhat more difficult, as our patients who recovered were soon restored to an Army convalescent home. It is very much easier to carry out this form of treatment among soldiers, particularly when one is dealing with considerable numbers, than among civilians even in a hospital. At first we believed that there was considerable difference in the donor's blood in regard to the supposed immune body content, as had been suggested by McGuire and Redden.[1] That they would vary in this property is only logical, but we are rather doubtful at the present time that this is really the explanation of the poor reactions in certain cases. In our opinion it is more likely that the secondary invading organism had begun to develop its lesion in the lung and that a new and subsequently fatal factor was added. In this district it is almost entirely the pneumococcus. From the data at hand, we cannot state that there is a noteworthy difference among donors, in regard to the clinical results produced by the injection of their blood. Those having a leukopenia or a leukocytosis and those who pursued a mild or severe clinical course seemed about the same.

---

[3] Christian, Henry A.: Incorrectness of the Diagnosis of Death from Pneumonia, The Journal A. M. A., Nov. 9, 1918, p. 1565.

The leukocyte count followed very closely a general rule. A leukopenia of from 3,000 to 5,000 was present at the onset of the influenza in a vast majority of cases. With the onset of pneumonia a very moderate leukocytosis, one of from 9,000 to 12,000, occurred in the majority. At times it was higher. We had, however, but eight counts between 20,000 and 30,000 in the 150 counts estimated. This finding is in marked contrast to that observed in the lobar pneumonia.

In some, particularly the very severe pneumonia cases, the leukopenia persisted throughout the course. A drop in leukocytes was a serious prognostic sign during the course of the pneumonia. We have very slight evidence of an influence on the leukocyte count by the blood transfusion. In two or three cases the increase was well marked, from 5,000 to 10,000, but in the remainder there was very little change, whether we began with a leukopenia or a moderate leukocytosis.

SUMMARY

The use of citrated blood from convalescent influenzal patients administered to patients when pneumonia followed the influenza appeared to have a decided beneficial effect, particularly if given early. Beyond the third day of the pneumonia it was of little value.

That the citrated blood establishes an immunity to *B. influenzae* is inferred but not proved. Many additional factors may play an important rôle. Extensive work along these other lines was conducted by the University of Pittsburgh during the recent epidemic, a report of which will appear later.

Suggestion by the Patient.—We are often misled by our patient's interpretations of his own case. In other words, we are human and subject to the power of suggestion. Often we are informed that they are suffering from heart disease, kidney or liver disease, or appendicitis, constipation or diarrhea, and we listen to their story and become hypnotized ourselves and follow along the line of the patient's suggestions. They are anxious to tell somebody their symptoms and if we are good listeners they are willing to pay us for our trouble and time for listening.—President's Address, Minnesota State Medical Society.

Clinical Notes, Suggestions, and New Instruments

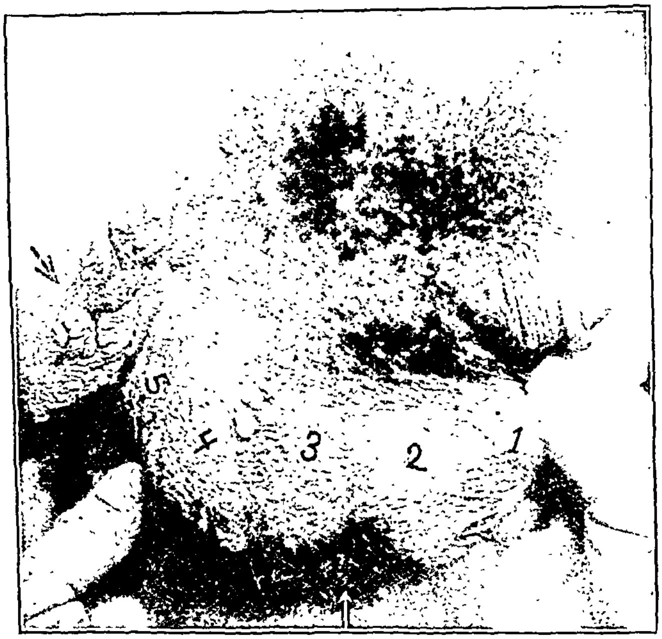
ONE MAN WITH FIVE TESTES: REPORT OF CASE

George H. Day, M.D. (Louisville)
Major, M. C., U. S. Army; Camp Venereal Officer.
Camp Pike, Little Rock, Ark.

This case was referred to the urologic department, July 1, 1918, for confirmation by Major H. C. Loos, chief of the surgical service at Camp Bowie.

The man in question was discovered by Major Loos at a local garage, where he was employed as a mechanic. After questioning the man and hearing his history, Major Loos was interested enough to have him report to the base hospital for examination. The case has since been presented to the Clinical Society of the Base Hospital, Camp Bowie, for examination.

G. E. M., aged 19, of San Benito, Texas, presented a negative family and personal history other than that his father had died of typhoid ten years before.



Scrota with five testes: white arrow points to line of demarcation between scrota; black arrow, rudimentary scrotum; 1, 2, 3, 4, 5, testes.

He had had gonorrhea twice, the first time at 17 years, and again six months before we saw him. The first time he knew he was other than normal was two years before, when on attempting to enlist in the service, he was rejected at Brownsville, Texas, by the recruiting officer of the Twenty-Sixth Infantry. At that time he was told that he was ineligible on account of severe varicocele.

He attempted to enlist again at Oklahoma City one year later with the same result.

Three months before he again attempted enlistment at Fort Worth, Texas, and was again rejected with a diagnosis of varicocele and hydrocele.

The man was well nourished, and aside from being overdeveloped, with the contour of the arms rather feminine and the pelvis and hips somewhat large, he appeared to be normal.

It was immediately noticed that the scrotum was much larger than usual. The penis was about twice the size found in boys of this age.

On retracting the scrotum it was noticed immediately that the young man had another normal scrotum and perhaps a third, which was rudimentary in origin, to the right of the normal one. On further examination four normal testes were discovered, two being in each of the two scrota and another atrophied one being in the redundant tissue posterior to the second pair. The third or rudimentary scrotum in the groin (right) contained no trace of the sixth, and may possibly be intra-abdominal. The line of demarcation in the tissue of the scrotum was most marked and showed forcibly the fact of the scrota.

When he assumed the knee-chest position, the posterior view strikingly brought out the line of demarcation between the scrota. Aside from an overabundant sexual desire he said he had never noticed anything abnormal in his sexual life.

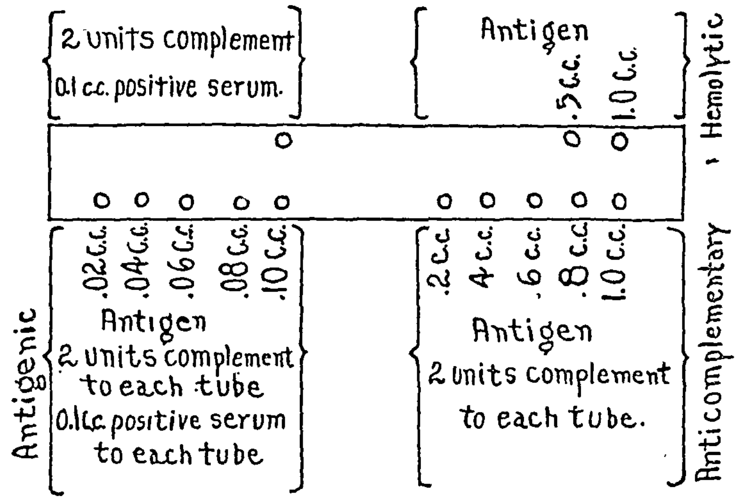
We have not had the opportunity of looking up the literature on the subject and are presenting it simply as an anatomic freak. Certainly the man is possessed with four normal testes and cords, a fifth atrophied testicle and perhaps a sixth which is undescended.

It would be interesting to see a section to note where the attachment of the second set joins the vas of the first, and it is not at all improbable that he has also multiple seminal vesicles, although only one prostate is palpable.

A SHORT METHOD OF MAKING NOGUCHI ACETONE-INSOLUBLE ANTIGEN

G. A. Magnusson, M.D., Seattle

In order to gain the most information from the Wassermann test, more than one antigen should be used in the "set up." One of the antigens so used should undoubtedly be the Noguchi acetone-insoluble, as it will give positive reactions with a higher percentage of syphilitic serums than the alcoholic extracts, while it is less likely to give false positive reactions than the more sensitive cholesterinized extracts. But its preparation requires so much time that this becomes quite a factor in a laboratory where considerable quantities are used. With a view of hastening the process of extraction and evaporation we tried this at higher temperatures and find that boiling temperature in no way interferes. In this way we can prepare and titrate an antigen all in one day.



"Set up" used in titration.

PROCEDURE

To one part of finely minced beef heart, nine parts of commercial ethyl alcohol are added. (We have recently tried the extraction with denatured alcohol and this seems to do as well. As alcohol is denatured according to varying formulas, some may not be usable.)

This is boiled in a water bath for from ten to fifteen minutes, and filtered while hot.

The filtrate is evaporated over a boiling water bath until the alcohol and water are removed.

The residue is extracted with a small amount of ether.

The ethereal extract is poured into a centrifuge tube and centrifuged until the supernatant liquid is perfectly clear. This is added to ten volumes of chemically pure acetone.

The precipitate is allowed to settle. The greater part of the acetone is decanted, and the rest is poured into a clean graduated centrifuge tube and centrifuged for five minutes at moderate speed, the acetone poured off, and drained thoroughly.

To the precipitate, ten volumes of chemically pure methyl alcohol are added, and the mixture is stirred with a glass rod until as much as will dissolve has gone into solution and then centrifuged until the supernatant liquid is perfectly clear. This is poured off and kept in a clean, well stoppered bottle.

TITRATION OF ANTIGEN

An emulsion is made with one part of this stock alcoholic solution and nine parts of physiologic sodium chlorid solution.

Titration is performed for antigenic, anticomplementary and hemolytic properties.

The accompanying chart illustrates the "set up" used in titration.

To each tube, physiologic sodium chlorid solution is added to bring the volume to 1.5 c.c.

Incubation is performed for one hour.

To each tube 0.5 c.c. of sensitized sheep cell suspension (5 per cent. sheep blood cells and 2 units of amboceptor) is added.

Incubation is performed for one hour.

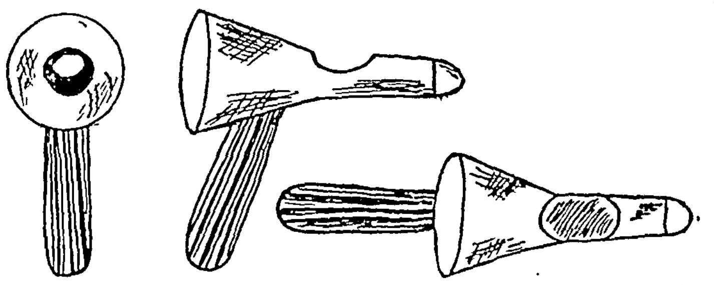
Most of the antigen preparations we have made in this way have had an antigenic unit of 0.02 c.c. of the 1:10 emulsion, while a full cubic centimeter was neither hemolytic nor anticomplementary.

TREATMENT OF CHRONIC GONORRHEAL SKENITIS WITH THE ELECTRIC CAUTERY*

Chester B. Moore, B.S., M.D., San Francisco

A not uncommon pelvic focus for the lodgment of the gonococcus is the gland of Skene. In this minute epithelial pocket such an infection may persist indefinitely in spite of local applications. Even if the ducts are exposed and medicinal injections directed into them with a hypodermic needle, the infection may continue without interruption. Often it is possible to express a few or several drops of pus week after week, and month after month, along with such oft-repeated treatment. Furthermore, this minute gland may remain in a chronic state of suppuration without a local symptom, the focus of infection being discovered only in the course of a general pelvic examination. Unless one makes an attempt to express the contents of these ducts, this focus may be entirely overlooked. In this type of gonorrheal infection of Skene's gland nothing less than the complete destruction of the gland will terminate the disease in this locality. This destruction may be easily attained by the use of the thermocautery.

The operation is quite easy and simple, provided one can get a good exposure. For this purpose I take a Kelly endoscope that has been cut off at the proper length so that it will not extend into the bladder, close it with the olive tip, and cut out a small window as shown. I have found that a No. 8 endoscope serves the purpose very well. This makes an instrument, a skenoscope, with a handle that is directed upward out of the way; the entrance is expanded to hold back and protect the labia; the tubal portion protects the urethra except at the point of attack, the gland, the ducts of which protrude into the window cut for the purpose. Under local anesthesia, it is possible to pass a small wire thermocautery into the gland without fear of cauterizing any other place than that desired. In order to obtain good light, I have had a small post so placed on the handle that it will carry an E. S. I. light directed toward the aperture. However, any means for obtaining good light will do.



Front, side and top views of instrument devised for use in the treatment of chronic gonorrheal skenitis with the electric cautery.

To cauterize the gland, as much discharge as possible is expressed from the ducts. The urethral entrance is cocainized with a 10 per cent. solution for about ten minutes. The instrument is passed, handle upward, until a good exposure is obtained. The entrance of the ducts is sought with a large size hypodermic needle, from which the point has been filed, or with the wire contained in the tubal portion of the instrument. The needle or wire is passed along the duct to the base of the gland. They will act as a guide to direct the passage of a small, pointed, electric thermocautery until as much tissue as desired has been destroyed. Up to the present, no discomfort or ill effects have followed this procedure. If the first operation has for any reason been unsuccessful, it may be repeated. Also, it is possible to cauterize the glands without passing a wire for a guide.

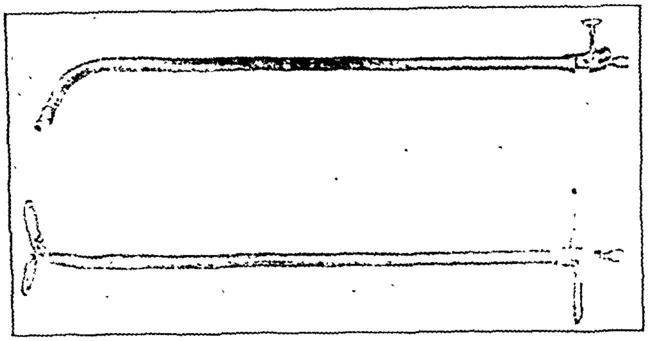
A NEW PROSTATIC TRACTOR *

A. J. Crowell, M.D., Charlotte, N. C.

While performing a seminal vesiculectomy some time ago, it occurred to me that the operation could be greatly facilitated by the use of a tractor inserted into the bladder, through the urethra, which has the same curve as that of a sound. For this purpose I therefore designed the one shown in the accompanying illustration.



Prostatic Tractor.

It consists of two fenestrated blades attached to shafts, the inner one of which has a cable in the curved portion which allows one of the blades to revolve around the other. There are two handles at the outer end of the shaft which regulate the rotation of the blades after insertion into the bladder through the urethra. When inserted, the handles are rotated from each other to open the blades within the bladder. The gland is thus pulled into the operative field and at the same time the handle of the instrument is out of the way of the operator.

A glance will show the superior advantage of the curve in any operation on the perineum when a guide is needed to locate the urethra, prostate, seminal vesicles or bladder. We use it as a routine in perineal prostatectomies and find that by its use it is much easier to expose the prostate, and the danger of getting into the rectum is greatly diminished.

After the tractor is inserted and the blades opened, slight pressure on the handle by an assistant will pull the gland well into the operative field. It is a better guide than the sound ordinarily used for this purpose. It gives not only a urethral guide that is fixed but also a definite location of the prostate gland and membranous urethra, which are firmly held in one position while the gland is exposed.

Elimination of Inhaled Dust.—In a paper read before the Institute of Mining Engineers on dust inhalation and the health of miners, J. S. Haldane, F. R. S., among other things said that investigations had shown that coal and shale dust were rapidly eliminated from the air passages by special dust collecting cells which phagocyted the dust particles and then carried them away. This, however, does not occur to the same extent with quartz dust, and whereas miners in coal and shale suffer practically no injury from the dust itself, quartz mining results in serious respiratory difficulties, both on account of the sharpness of the dust particles and because of their defective elimination in the manner described. The widespread introduction into coal mines of stone dusting as a means of preventing coal dust explosions has directed attention to the possibility of injury from this cause.

Military Medicine and Surgery

THE TREATMENT OF HYSTERIA

SUCCESSFUL RESULTS OF A RAPID REEDUCATION METHOD

JULIAN MAST WOLFSOHN, M.S., M.D.
(San Francisco)
Captain, M. R. C., U. S. Army; Assistant Professor of Medicine, Leland Stanford Junior University School of Medicine
LIVERPOOL, ENGLAND

The world war has provoked such an immense number of the various types of hysterical disorders that the conception of hysteria can now be studied more easily from every aspect. It has taught us to look on what we ordinarily designate "hysteria" as merely the outward sign, the symptom, of the fundamental causative factor—the hysterical psychic background. So, when we speak of the treatment and cure of these patients, we wrongly say we have cured the hysteria; we have cured only the hysterical symptom. What most physicians in their ardor have left untouched and untreated is the hysterical psyche which gave rise to the symptom which has incapacitated the patient. This is important to remember when the question arises of returning a hysterical subject to the same environment that originally caused the hysterical symptom.

The war has also shown us that hysteria seldom, if ever, occurs during violent emotion, but rather during the contemplative stage succeeding the emotion; also that there is no essential difference, except perhaps in the number and in the intensity of the emotion produced, between the hysteria of warfare and that of civilian life.

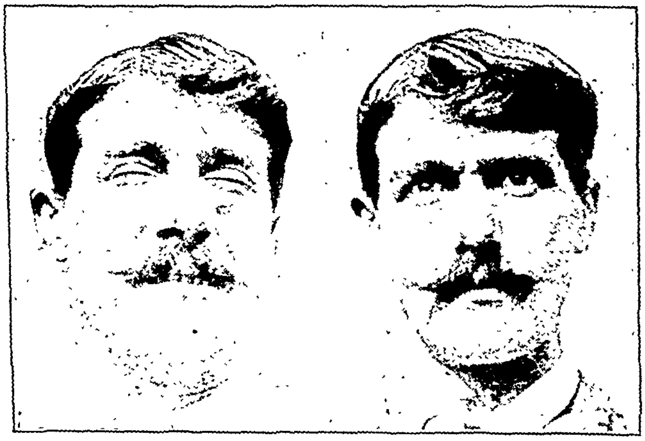

Fig. 1.—Patient before and after treatment for hysterical blepharospasm.

Babinski has so far offered the clearest and most concise definition of hysteria: "Hysteria is a pathologic state manifested by disorders which it is possible to reproduce exactly by suggestion in certain subjects and can be made to disappear by the influence of persuasion alone." Instead of "hysteria," which is obviously a misnomer, he has substituted "pithiatism," which means the possibility of being cured by the influence of persuasion.

There have been published volumes on the classification of hysterical disabilities, but very little on their treatment. In Babinski's book on hysteria, for example, eight pages are devoted to the treatment and 252 to other desiderata on the subject.

It is with the idea, therefore, of presenting to the American physician, especially to him who is going into active service, the results of my studies on this subject in British and American hospitals in England during the past year, and to give the outstanding features I have learned for the successful and rapid cure of this class of case, which accounts for an important percentage of the discharges from the fighting armies, that this paper is published.

This paper is based on 573 cases of hysteria treated by me in British and American hospitals; in the former are included those hysterias largely due to "shell shock," in the latter those found in ordinary civilian life. Of these, 550 patients, or 95 per cent., were cured of their disabling symptoms completely.

I shall not deal with the causes or analysis of the different types of hysteria, nor consider the subject of relapses, of which I am now collecting full data. The symptoms included in the 573 cases are given in the accompanying tabulation.

Occasionally more than one hysterical symptom would be found in the same patient. This has swelled the actual number of symptoms treated to 605.

Only twelve of the 550 patients had external wounds complicating the picture. In only two patients were there any concomitant organic nerve changes noted.

In more than 90 per cent. of the cases the cure was accomplished within the first twenty-four hours. The extremes varied from five seconds in some of the aphonics to more than seventy-two hours in some of the dysbasias of long standing.

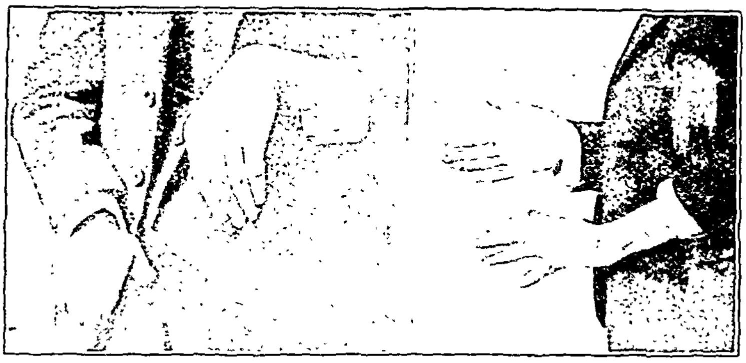

Fig. 2.—Functional flaccid wrist drop in a case of hysterical monoplegia of ten months' duration cured in ten minutes.

The most important part of the treatment is the confidence of the physician in the correctness of his diagnosis and in his ability to produce a cure. This air of assurance spells immediate success. No one can convince others who himself is unconvinced.

SYMPTOMS INCLUDED IN FIVE HUNDRED AND SEVENTY-THREE CASES

	Cases		Cases
Mutism	84	Tics	8
Deafness	30	Astasia abasia	4
Aphonia	175	Stasobasophobia	20
Stammering	118	Dancing gait	6
Blepharospasm	2	Hemiplegias	9
Blindness	6	Tremors	40
Monoplegias	46	Photophobia	2
Paraplegias	54	Double platysma spasm	1

One can divide the various kinds of treatment of hysteria into two groups, the slow and the rapid. Among the former are:

1. The purely reeducative methods, for example, breathing exercises and singing in the stammering cases, and the use of mechanical machines, massage, etc., in the paralyses. I have watched stammerers thus treated for as long as three months and paralytics given electrical treatments for six months by "kindly" nurses and sympathetic teachers with very gradual improvement, if any, and have repeatedly cured these patients of their symptoms in one sitting of from one-half to one hour.

2. Psychotherapy, consisting of psychanalysis. This is impracticable for the hysterias of warfare at this time. It often accomplishes much in the psychoneuroses, in which the emotive processes are in the ascendency, but there are not enough psychoanalysists to deal with the cases of one large hospital for this form of disease. The method is too slow to be of practical use when dealing with such large numbers of patients. One must have recourse to rapid methods by which the patient is quickly cured of his symptoms after a short preliminary psychologic survey. After his cure, the patient is more willing to discuss causes and he often tells things surprisingly pertinent when the confidence in his physician is supreme.

Thus an early accessibility to the patient through a rapid cure is accomplished by any of the following methods, which include:

1. Hypnotism. This was used extensively, especially at the beginning of the war, but its use has been discontinued by most physicians on account of the frequent relapses and otherwise indefinite results. However, hypnotism is very valuable in treating insomnia, and I have used it successfully in combating terrifying dreams and hysterical convulsions.

2. General anesthesia with ether, combined with strong suggestion in the excitement stage. This is still frequently used, but I believe that on account of the discomfort to the patient, simpler methods should be employed first. The method finds its most successful use in the intractable cases of hysterical deafness.

3. The continuous bath. This is reputed to have been quite successful in the treatment of certain algias and motor disturbances of hysterical origin.

4. Suggestion. The best of all treatments in my hands has been strong suggestion, reinforced by some mechanical agent which will assist in relieving at least some of the disturbed functions. This is easily administered with the aid of faradism or galvanism, and the results are quick and complete. Thus Yealland has aptly described the three principles he employs. (A) Suggestion, in which the patient is made to believe he is curable and from this springs the belief that he will be cured. This is briefly done and is followed by (B) Reeducation, which is continued without pause until the disordered functions are brought back to normal. (C) Discipline, in the form of demanding a military atmosphere and regular duties. This breaks down the unconscious resistance of the patient to the idea of recovery. The last is the real preventive of fixed ideas and is a most constructive policy.

SPECIAL TREATMENT FOR THE VARIOUS DISORDERS

Hysterical Mutism.—All of the eighty-four patients treated were cured within an hour, some requiring only a few minutes. In the uncomplicated cases of mutism, strong suggestion combined with faradic stimulation of the sides of the neck in increasing strength, the patient at the same time being shown how to produce the vocal sounds "e," "ah," "a," etc., usually suffices to produce articulation quickly. The patient then learns how to adjust his tongue to utter a squeak, which, as a rule, is rapidly followed by letters, especially the labials and dentals, then numbers, the months of the year, and finally sentences. If a hypesthesia or anesthesia over the trachea is found before treatment, it is used as a lever for further suggestion because the disturbed sensation can be easily removed by the faradic brush.

Case 1.—J. J. L., rifleman, who had hysterical mutism ten months, was cured in one minute by suggestion, combined with faradism to the sides of the neck. During an air raid in July, 1917, an aerial torpedo burst 50 yards away from the patient. He was rendered unconscious and cannot remember how long he remained so. He had been mute since then and could not even protrude his tongue. He was treated in several hospitals without success.

These patients with mutism (and this is true for all hysterical symptoms) who have passed from hospital to hospital, receiving suggestion after suggestion, who have seen many physicians or who have had the most varied and unsuccessful treatment, are the most difficult to cure on account of the fixation of the idea of incurability. The physician has to have an ever-ready plausible answer for myriads of questions, and especially to statements that the sufferer has had all these treatments before.

Hysterical Deafness and Deafmutism.—If deafness is associated with mutism, it is well to treat the deafness first. The mutism often disappears soon after the return of hearing. Sixteen of the thirty cases of deafness were accompanied by mutism. In only one was there failure to cure, and this was undoubtedly due to interruption of the treatment, and its continuation by a third party.

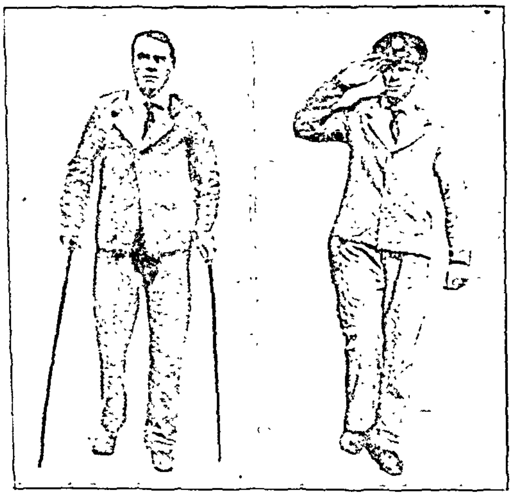

Fig. 3.—Patient with rigid hysterical paraplegia of nine months' duration cured in forty minutes.

It is well at first to write down the orders for the patient, so that he will understand and pay attention to them. The deaf hysteric can usually hear very high-pitched and shrill sounds which he is unable to interpret.

Inserting a stethoscope into the ears of the patient, different tuning forks of various vibration lengths are quickly and successively held at the bell of the stethoscope and the patient told to nod when he hears something and to reproduce the sound heard. When he can finally do this for low notes, the voice of the operator is then substituted for the tuning forks and, beginning with a loud voice, the distance between the patient and operator is gradually increased. Then the loudness and pitch of the voices are diminished. Finally the stethoscope is removed and one ear is blocked. The patient is told to repeat quickly the things he hears while the operator rapidly changes his voice from loud to soft and then to a whisper, while he gradually increases the distance from the patient until the latter can hear the whispered voice from 10 to 20 feet away. If one tests the bone conduction by applying a tuning fork over the mastoid region, the patient receives some intimation that he is not completely deaf. This is used as an auxiliary suggestion, however, and is followed by the treatment outlined above.

Case 2.—Private H. H., aged 26, who had hysterical deafness four months, was cured in fifteen minutes. He was in a dugout when a high explosive shell burst outside. He was knocked unconscious and remained so until he awoke the next day in a casualty clearing station and found that he was deaf and dumb. Several days later he regained his speech but not his hearing. He had considerable temporal headache, but there were no objective signs of injury to the auditory apparatus. He had been treated in three hospitals in France and England without improvement. Examination revealed bone conduction to high pitched notes only. No air conduction could be elicited. The treatment was carried out as outlined above, and the patient could hear the whispered voice at 15 feet in fifteen minutes.

Hysterical Aphonia.—One hundred and seventy-five aphonics were treated with 98 per cent. of cures. In many of these cases the symptoms followed gassing, with its subsequent laryngitis and aphonia. After the inflammation has subsided, the aphonia continues, sometimes indefinitely. Often a shock or sudden emotion, such as a terrifying dream, falling out of bed, or even a severe reprimand may suffice to bring about a "cure."

The vocal cords of an aphonic should always be carefully examined prior to treatment. If these look normal other than failing to approximate equally on attempted phonation, it is well to tell the patient that he is about to get his voice back immediately. Then, very often, simply gargling with a 10 per cent. salt solution is sufficient for the patient to be able to make an articulate "ah." He is then quickly reeducated in mutism. Sometimes tickling the soft palate with the tongue held protruded will produce the same result, but these failing, faradic stimulation of the sides of the neck, as in mutism, practically always cures in a few minutes.

Case 3.—Private B., aged 19, who had hysterical aphonia ten months, was cured in three minutes. The patient lost his voice in May, 1917, following gassing and a cold. He had not spoken above a whisper since. He had not been worse or better since the onset. He suffered from easy fatigue and frontal headaches, and trembled in air raids. He feared dark places and heights. His concentration was poor. He always possessed a nervous temperament and had two or three bad frights in childhood. He was a total abstainer and suffered from depression of spirits. This patient was treated with the roller faradic current.

Hysterical Stammering.—In some cases, as in mutism, the patient is cured of his original hysterical symptom either spontaneously or by incomplete treatment, and then lapses into another and worse condition—stammering. In fact, the usual sequence of events is unconsciousness, mutism, aphonia and stammering, although any of these may occur without the others having been present first.

One hundred and eighteen cases of stammering were treated. While most of these patients (90 per cent.) were cured at the first or at the most at the second sitting, some were not cured till the third or fourth—especially those with marked tremors or fear reaction, or those who were easily startled or had other signs of emotivity About 50 per cent. of these cases stammer a little for some months afterward when they become embarrassed or excited; in other words, so long as there is any emotivity left. In letters I am receiving from patients treated, they tell me this symptom gradually wears off and that they are regaining their self-possession.

Case 4.—Private B., aged 23, who had hysterical stammering fourteen months, was cured in ten minutes. Jan. 15, 1917, the patient was blown up. He was unconscious for two or three days, followed by mutism for several days, which was relieved spontaneously and was succeeded by marked stammering, which persisted in spite of many attempts at cure by various methods. The family and personal histories were negative. He was cured by suggestion and faradism.

Hysterical Blepharospasm.—Both of the patients with blepharospasm were cured within a minute each by the application of a faradic current over the supra-orbital notch first on one side and then on the other, immediately after strong suggestion. The blepharospasm was the result of gassing and photophobia. In one case (Fig. 1) the blepharospasm had been present seven months and was cured in ten seconds.

Hysterical Blindness.—Of hysterical blindness, seven cases were treated and cured at one séance each. In these cases the intelligence and cooperation of the patient are essential for the rapid cure.

Case 5.—Sergeant L., aged 28, who had hysterical blindness four months, was cured in two hours. A letter to his nurse explains the treatment tersely and lucidly.

> Dec. 3, 1917, I was blown up by a German 11-inch shell while bringing ammunition out of the line, and within a few days I completely lost my sight. I was treated at the —— Hospital for two months. I had electric treatments for about ten days. I was forbidden to smoke and had both eyes bandaged for some days. No good results were obtained, and I was sent to —— Hospital, Feb. 15, 1918. Here I was examined by three or four doctors and remained there for three weeks. My sight was no better and in consequence I was sent to —— Hospital. I was again treated by four or five doctors with the electric apparatus for about a month, but no improvement. I had lost confidence and was beginning to lose hope of ever being able to see again. Then Captain W. visited me and after explaining what was the matter with me and the reason I could not see, he treated me with the electric power for about an hour, leaving me just before 2 o'clock; but being interested in my case, he came back, explaining to me that he felt sure he could benefit me that afternoon. He gave me electric treatment again and after about half an hour I gradually was able to see first a light, and then his hand moving in front of my eyes. Further treatment and I was then able to see out through the window in my ward and plainly see a house and describe it in detail. I was, in fact, able to see quite well after his treatment that afternoon. Although the treatment was a little painful, I had every confidence that the doctor was doing his utmost for me, and getting back my sight was worth ten times the pain and discomfort.

This patient from complete blindness had $^{20}/_{20}$ vision at the end of two hours' treatment. There was no resulting constriction of the color fields. Three months later, a letter from the sergeant says his eyesight is as good as it ever was.

The hysterical paralyses of the motor apparatus treated include forty-six monoplegias, fifty-four paraplegias, and nine hemiplegias. The treatment was practically the same in each of these cases, although it was found that the longer the duration of the paralysis, the more difficult was the cure. If, on the other hand, sensory disturbances, such as anesthesia or dysesthesia (which is always associated in the lay mind with the loss of power) were found, it was easy to remove the sensory disturbance by suggestion or by the faradic brush, or by both, and then resort to rapid reeducation. As a rule, the sufferer from a hysterical paralysis, sensory or motor, gives a history of its onset shortly after a slight wound or having been blown into the air, or even landing against the wall of the trench, experiencing a pain in the back or numbness in the affected extremity.

Case 6.—Lieuenant B., aged 26, who had hysterical hemiplegia eighteen months, was completely cured in forty minutes. In September, 1916, he was knocked on the right side of the head and was unconscious for ten days. On regaining consciousness he was paralyzed on the left side of the body. There were no sphincter disturbances. Speech was normal. He felt as if the whole side of his body were dead and did not belong to him. He could not move the muscles of the left arm or leg. Practically no improvement occurred until June, 1917, when he was knocked over by a tram and was unconscious for two hours. On the following day he regained some of the power in the muscles of the left side of the body, but the numbness remained. On examination, loss of superficial and deep sensibility of the left half of the body to the midline was found. The deep and superficial reflexes were normal on both sides. The fields of vision were normal. The patient was treated by electrical suggestion. This patient is a professional musician and the same day, after the cure, practiced his violin for five hours, the first time in eighteen months.

Case 7.—Gunner J. W., aged 25, who had hysterical paraplegia five months, was cured in forty-five minutes. The onset occurred in October, 1917, while the patient was in a bivouac. An aeroplane dropped a bomb just behind him. After the explosion he found his friend with his head half severed from the body and he remembers no more. He slept badly, had continual frontal headache, and when he thought of the unfortunate episode he went into a general shaking convulsion. He had not been able to stand for six months. Neurologic examination revealed both legs very rigid, and any attempt at voluntary movement resulted in marked coarse general tremor. The reflexes were increased throughout. The Babinski reflex was negative on right and left. There were no sensory nor sphincter disturbances. After continuous treatment for three quarters of an hour the patient was able to walk normally.

Case 8.—Private S., aged 22, who had hysterical monoplegia five months, was cured in five hours. In December, 1917, he had cerebrospinal meningitis, for which many lumbar punctures were performed. During one of the punctures he felt a numbness in the left leg. He was able to perform his regular duties until March, 1918, when, during a march, he felt dizzy and fell unconscious to the ground. On recovering consciousness two hours later, he was unable to move a muscle in the left leg below the groin. It felt "as if it did not belong to him." On admission to the hospital, he walked with the aid of two crutches and dragged the left leg as if it were stuck to flypaper. Deep and superficial sensibility were profoundly disturbed below the level of the umbilicus front and back, to the left of the midline. Articular sensibility and likewise vibration sense in the same area were not perceived. The knee jerk, Achilles jerk and superficial abdominal reflexes on both sides were normal. The Babinski reflex was negative on both sides. There was complete inability to move a single muscle of the left leg below the groin. The patient was treated by suggestion and faradism for five consecutive hours, at the end of which time all sensory disturbance and muscle weakness had disappeared. He now walks normally.

Sometimes a true hysteria follows a severe wound. In this case the hysterical symptoms are superimposed on the organic but do not disappear *pari passu* with the healing of the wound. It is here that the greatest difficulties in diagnosis try the physician.

Case 9.—Captain W., aged 28, who had an organic lesion of the brachial plexus with hysterical paralysis of the upper extremity, after healing of the wound, for twenty-four months, was cured in twenty-five minutes. He had received a gunshot wound through the left infraclavicular space, the bullet emerging through the scapula behind. An aneurysm of the left subclavian artery resulted, which was later ligated. The brachial plexus was also injured, but the torn nerves were sutured. The whole left arm was paralyzed, but the patient gradually became able to move his arm so that with great effort the fingers could be made to twitch. Similar movements of the forearm were possible, after effort. Examination of the left arm revealed practically no radial pulse, and a slight general atrophy. The reflexes were all normal. There was marked general muscular weakness. Sensibility was impaired for touch and pain below the shoulder girdle. In twenty minutes the patient was practically cured, except for a slight weakness of his little finger, which remained in slight abduction. He was returned to his command on his urgent request in two weeks.

Hysterical Disturbances of Gait.—Various authors have described and given names to different types of disordered gaits. So far as treatment is concerned, it is the same in each case, namely, strong suggestion with or without faradism, followed by rapid reeducation. In this series there were thirty cases, including four by astasia abasia, twenty of stasobasophobia, and six of dancing gait.

Case 10.—Private J. P., aged 20, who for five months had stasobasophobia, with relapse after violent emotion, was cured in seven minutes. In September, 1917, he was blown up and was unconscious for twenty-four hours. He awoke in a casualty clearing station. He was unable to speak, had tremors, walked in his sleep, had terrifying dreams and suffered from severe occipital and frontal headaches. A few days later he recovered his speech, but talked with a stammer. He was treated by hypnotism and electricity and was sent back to his unit in December, 1917. On his journey back, which occupied six days, he was spending the night in a rest camp when a bomb dropped and exploded within a few feet of the patient while he was in bed. He was extricated from the wreckage, but was unable to walk. He was dazed, stammered, and complained of pains in the head and in the base of the spine. His legs felt numb and cold. He said he received "very harsh treatment with electricity and very little improvement" in two hospitals. He cured himself of stammering by reading aloud. Examination was negative except for inability to maintain the erect posture, and fear of falling unless he had two crutches to aid him to stand. All muscular movements were executed fairly well in bed. A five minute "straight talk" and two minute treatment with the faradic tetanic current sufficed to enable the patient to walk and to run in a perfectly normal manner. That day the patient took a 2 mile walk after lunch.

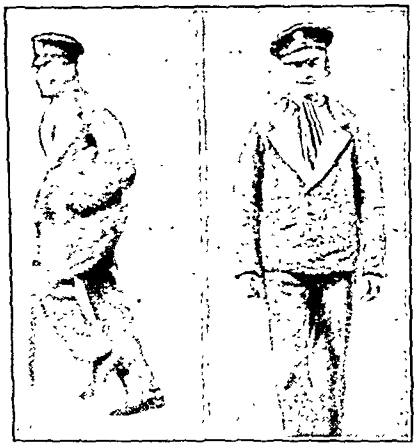

Fig. 4 (Case 11).—Patient with dancing gait before and after treatment.

Case 11.—Private G. A., aged 21, who had dancing gait nine months, was cured in twenty minutes. The patient was blown up and was subsequently unable to stand for several weeks. Since then he had great difficulty in maintaining his balance even with the aid of a cane. He staggered a few steps to the right and as many to the left. At times he would halt suddenly and take a double shuffle to the front. When he lay on his bed he could execute all movements of the lower extremities very well. There were no neurologic disturbances of note. With the faradic current and strong suggestion the patient was able to get on his feet in ten minutes, and in ten more minutes of reeducative exercise he was walking.

Hysterical Tics, Tremors and Convulsions.—The forty cases of hysterical tics and tremors represented all the stages from a slight, coarse tremor which occurred during excitement or effort to the involuntary coarse jerking of the greater part of the body, worse on effort and even persisting at rest, but disappearing during sleep. Since emotivity is largely an accompaniment of these disorders, rest, strict isolation and continued suggestion must be employed to a great extent in the treatment. I have always considered stammering merely a form of functional tremor, for here also emotivity plays a leading rôle in its production, much more so than in the functional paralyses without tremor. In most cases the coarse tremor can be removed in a short time; but it is always necessary to study the patient psychologically for a shorter or longer period before treatment. The use of suggestion alone is very potent as a cure, but it is greatly enhanced by explaining to the patient in a terse, simple way, the rationale of the disability. As a prophylactic against relapses, physical exercises are indulged in for several successive weeks.

The tics are the most difficult of all the hysterical disorders to treat, as suggestion or even faradism rarely succeed rapidly in abolishing the disorder. In these cases, isolation, forced feeding and oft repeated corrective exercises before a mirror, together with strong suggestion, help naturally to cure this aggravating symptom. As the emotion subsides, the tic diminishes.

Sometimes, as in the following cases, one of double platysma spasm, the patient was cured after a very brief treatment.

Case 12.—Private C., aged 44, who had double platysma spasm four months, was cured in three hours of continuous treatment. He was buried in a dugout and was being extricated when another shell burst nearby. This unnerved him, and he began to shake all over. He was carried to a shell hole and remained there for several hours until the barrage cleared. He was shaking so badly that he could not walk without the aid of two men. On the way to the hospital that day, he was knocked unconscious again, and when he regained his senses his head began to twitch and had continued to do so since. The patient was depressed, and had terrifying dreams, continual headache and difficulty in getting to sleep. When he did get to sleep it was fitful. The feet and hands were cold and clammy, the pupils were dilated, the reflexes increased. There was a continual jerking of the chin and neck in a forward movement, about forty times a minute. Slamming of a door or sudden noise sent the patient into a long continued spasm with contortion of the face and mouth. After several days of complete isolation, during which he was given strong suggestion and many reassurances as to his imminent cure, he was finally treated with a mild faradic current and cured after three hours of treatment.

RULES OF TREATMENT

Having thus detailed the treatment, I have been led, through my experience, to lay down the following general rules for the efficient, rapid, and complete cure of hysterical symptoms:

1. Study each case fully. Take a complete family and personal history, especially for previous nervousness or similar attacks, even though the character of the affection appears evident.
2. Study each case psychologically, before instituting treatment. This can take the form of a psychanalysis in the cases in which emotivity plays a prominent part. Encourage

the patient to talk of himself and thus gage his mental condition.

3. Produce an atmosphere of cure in the wards or office. This is best accomplished by contact with cured patients. A confident, optimistic atmosphere has helped to cure more hysterical symptoms than all the mechanical appliances.

4. The patient must seek the cure.

5. When the patient resists the cure, this must be broken down by strong persuasion, long continued, or by faradism.

6. The physician must, at all times, be master of the situation. He must have a ready response to all questions put to him by the patient.

7. Do not discontinue the treatment until the cure is accomplished.

8. Let the patient into your confidence, and explain to him in simple terms how his symptom is caused and how you propose to cure it immediately.

9. Be absolutely sure of your diagnosis before beginning treatment.

10. A quiet, firm sympathy, together with an air of supreme confidence, is essential for the "air of recovery" in the treatment room.

11. Hysteria is often promoted in the ward by mental contagion. If a severely affected patient is admitted it is best to isolate him for a short while and thus prevent this contagion.

12. The earlier the treatment is instituted after the occurrence of the symptom, the easier and more complete the cure. The fixation of the idea is thus prevented.

13. During the treatment of a paralyzed member, watch for the slightest voluntary movement of the limb on the part of the patient and use that for the point for further suggestion.

14. The method of treatment varies with the mentality of the patient, the desire for recovery, the degree of education and his social level.

(*a*) To the cultivated and intelligent, frankness should be the keynote. Suggestion often suffices for the cure.

(*b*) To the uneducated, simple suggestion plus a material method is usually necessary.

15. To avoid the distraction of the patient during treatment, all extraneous noises and movement should be eliminated.

16. The physician must possess a strong will power. He cannot convince unless he himself is convinced. He must display kindness, but his commands must be full of authority.

17. Results of treatment depend on the physician who plays the leading part. The patients are cured when they find their master.

18. Do not lose your temper. Have patience.

19. Select the best time for treatment, and if not successful after a time, cease, and recommence at a more favorable opportunity, explaining to the patient that rest is the cause for stopping. Meanwhile he should be completely isolated.

20. Do not give fresh suggestion to the patient or threaten him unless he is known to be a malingerer.

21. The ease of curability is largely dependent on the duration of the symptoms and the nature and number of previous treatments.

22. Contractures are more persistent than paralyses.

23. Strict military discipline and regular outdoor work are the necessary after-cure of these patients.

24. Make the disease an unprofitable one for the patient.

25. The cure of a hysterical symptom is a mental combat between the physician and the patient, in which the victory is on the side of the physician. This is the secret of psychotherapy.

26. The patient should be observed for a few weeks after the cure.

27. The most potent causes of failure to cure are ill will of the patient, unfavorable surroundings, and mistakes in diagnosis.

With these considerations as working hypotheses, any physician should be able to treat hysterical disorders successfully; but without them, failure stares him in the face.

American Red Cross Military Hospital No. 4.

THE SURGICAL TREATMENT OF EMPYEMA BY A CLOSED METHOD *

ARVINE E. MOZINGO, B.S., M.D. (Tipton, Ind.)
Captain, M. C., U. S. Army
WASHINGTON, D. C.

The death rate from many hundred cases of empyema occurring in the United States Army during the winter of 1917-1918 was very high. The average mortality reported from the various camps was 30.2 per cent. Many camps reported between 45 and 60 per cent., and one camp reported a mortality of 84 per cent. in eighty-five cases.[1] Most of the deaths reported followed virulent *Streptococcus hemolyticus* infection. Whether or not this high death rate was due to the virulence of the infection or the treatment, it is evident that there are great possibilities for improvement in methods of treatment.

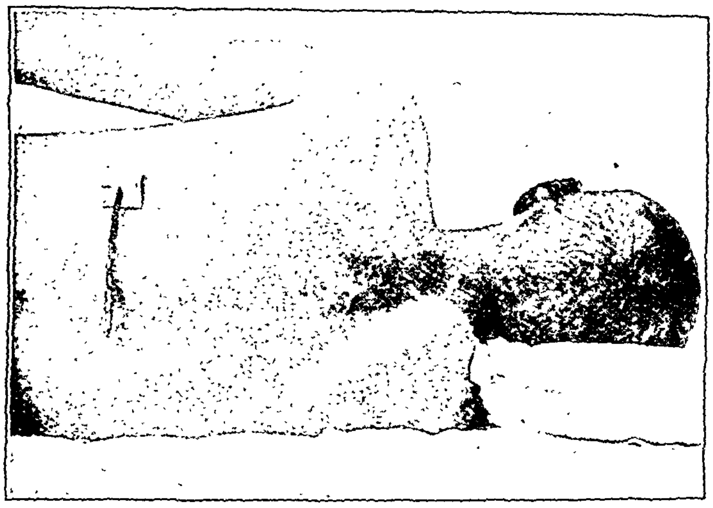

Fig. 1.—Tube inserted and fastened in place.

During the past seven months I have had the opportunity to observe seventy cases of empyema in the Walter Reed General Hospital, Washington, D. C., and as a result of this experience have adopted a method of treatment that is submitted as an improvement on the usual procedures. The chief features of this method are:

1. A single, early, minor operation without danger of shock or collapse of the lung.
2. Intermittent removal of secretion and antiseptic treatment given through a small rubber tube, with a bulb syringe.
3. Rapid partial sterilization with neutral solution of chlorinated soda (Dakin solution) followed by complete sterilization with a 2 per cent. dilution of liquor formaldehydi in glycerin.
4. Maintenance of negative pressure in the empyemic cavity, tending to early obliteration of the cavity.
5. One dressing which will last several days and no skin irritation.
6. Emphasis on simple physical principles rather than on major operative surgery.

DETAILS OF METHOD

If fluid in the pleural cavity is suspected, a diagnostic puncture should be made at once. If a smear from the fluid is negative, and the patient's condition permits, it is best to wait for a culture report. Care must be taken not to operate on a sterile cavity; but if pyogenic micro-organisms are present, operation should be done immediately.

---

* Read before the staff of Walter Reed General Hospital, Oct. 16, 1918.

[1] Cases of Empyema at Camp Lee, Va., Preliminary Report, by the Empyema Commission, The Journal A. M. A., Aug. 3, 1918, p. 366; Review of War Surgery and Medicine, August, 1918.

The location of the empyemic cavity is determined by physical examination, diagnostic puncture, and by roentgen ray when this is available. The place of election for operation is at the most dependent part of the cavity when the patient is either erect or recumbent.

If fluid is present in the ninth interspace, postaxillary line, this point is most desirable. The exact site of operation in this method is, however, not as important as in the usual thoracotomy procedures. The main point is to enter the cavity, preferably as low as possible. When operation is determined on, the field is sterilized and enough 0.5 per cent. procain injected intradermally to make a well blanched wheal the size of a dime and about 4 c.c. just between the ribs. With a knife, 6 mm. wide, a stab is made through the skin and then with a 7 mm. trocar and cannula the thoracic wall is punctured midway between the ribs so as to avoid the intercostal vessels and nerve.

The trocar is withdrawn and a finger immediately placed over the end of the cannula to prevent pus from escaping or air from entering. The finger is removed and a rubber tube instantly inserted through the cannula into the chest cavity. The tube, when introduced, should fit closely into the cannula and be held closed so that no air can enter, and should be long enough to extend from 2 to 6 inches outside of the cavity.

The cannula is now withdrawn and slipped off the tube, leaving the latter firmly held, air tight, in the chest by the contracting wall of the wound.

While the use of a trocar and cannula is to be preferred, it is not essential; and in case no trocar and cannula are at hand, a small stab wound should be made and the rubber tube carried into the pleural cavity by use of a curved hemostat.

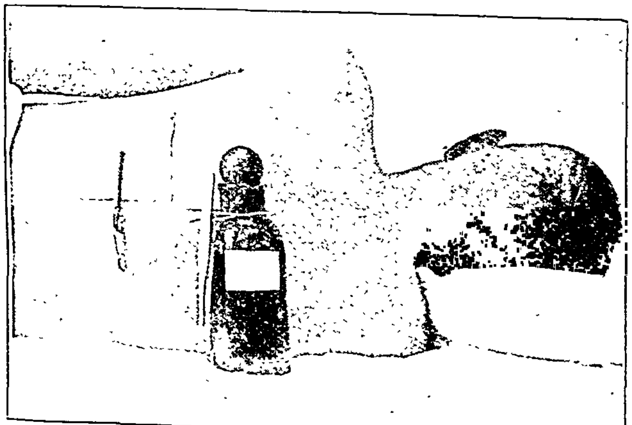

Fig. 2.—Finished dressing, bottle of Dakin's solution, and tissue forceps.

The length of the tube in the cavity depends on the shape and size of the cavity. If the cavity is small, the tube need be inserted barely through the thoracic wall. In large or irregular cavities, the tube can reach from 2 to 8 inches within, and should occasionally have a 2 mm. fenestra in the side at a point just inside the chest wall, in order more easily to make possible the aspiration of all fluid from the cavity.

The dressing is small and does not hinder free expansion of the chest. The tube once inserted is thus fastened in place: A 1-inch safety pin is thrust through the edge of the tube, so as not to obstruct the lumen. Between this and the skin is placed a thin pad of gauze, 1 inch square, split to the center (Fig. 1).

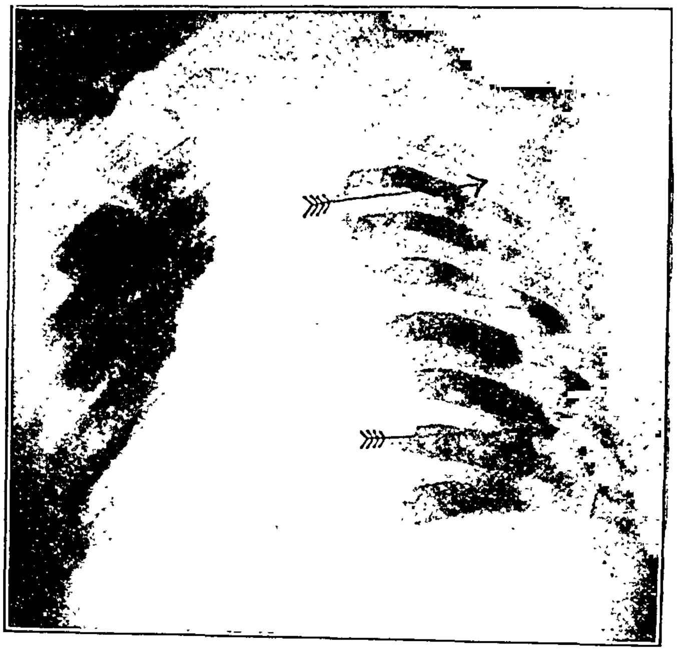

Fig. 3.—Empyemic cavity, containing air, outlined by heavy wall indicated by arrow, and with tube entering lower part.

On top of the pin is a similar pad with a split turned the opposite way. Over all is placed a pad 2 inches square, of ten layers of fine meshed gauze, in the center of which a hole to admit the tube snugly has been made with a rounded and pointed instrument and never by cutting. This pad is held by four strips of adhesive plaster, each 1½ inches wide and 3½ inches long, making the finished dressing a 3½-inch square (Fig. 2). This dressing will last several days, as no discharge escapes around the tube.

By means of a half-ounce bulb urethral syringe, all the pus is aspirated from the cavity through the tube, and reversely; the cavity is washed out with Dakin's solution. No air is allowed to enter the tube or, through it, the pleural cavity. To prevent entrance of air and contamination, the tube is kept closed at the tip end by a spring clip between treatments.

Each patient should have his individual syringe and Dakin's solution in a wide mouth bottle to which is attached a wire to hold the tissue forceps. During aspiration and washing out, forceps and not the fingers should be used to compress and close the tube each time the syringe is removed for emptying or filling it, to eliminate possible contamination.

In giving treatment, the tube is first compressed with the forceps, the clamp removed, the nozzle of the syringe inserted with the bulb compressed, and the secretions that have accumulated since the last treatment are aspirated. One has to make sure that the negative pressure is maintained by not allowing air to enter through the tube. When, by this means, all the secretions have been aspirated, the method is reversed and from 20 to 60 c.c. or more of Dakin's solution are injected, not instilled, into the cavity. For aid in cleansing, the solution is agitated in the cavity by quick compressions and expansions of the bulb. Aspiration is performed again and this process is repeated until the fluid comes away clear. Then the cavity is refilled to about one-half the original capacity, and the clamp is applied and left for from five to thirty minutes, during which *time the patient* should change his *position* frequently to make the contained mixture homogenous and bring the solution in contact with all the infected pleural surfaces.

The frequency of aspirations and injections depends on the general condition of the patient. Beginning *with the* operation, treatments are *given* every two hours by day and every three hours by night, until all the pyogenic membrane and fibrous exudate have been dissolved, a process which usually takes from one to four days, depending on the kind of infection, and which may be determined by the amount and color of the sediment. In *Streptococcus hemolyticus* infection, the membrane and fibrous deposits will require a longer time to dissolve than is usual with other infections.

If the pneumonic process in the lung is still active, the treatments should not be given *oftener* than every six to eight hours until the pneumonia subsides, as more frequent treatments will cause a reaction indicated by an increased rise of temperature and pulse rate. As soon as the pneumonia has subsided, the patient should be *allowed* out of bed, and as strength increases should be given deep breathing and light setting up exercises. With this method, it is not necessary to keep patients in bed in cases of uncomplicated empyema, or have them use Woulfe bottles.

While Dakin's solution, because of its free chlorin and alkalinity, is one of the greatest solvent bactericides in general use, its action is brief. In a series of cavities cleansed in the manner described above, and with 150 c.c. of Dakin's solution, testing 0.49 per cent. of free chlorin when first injected and kept agitated with a syringe, of which solution 10 c.c. were then withdrawn every minute for five minutes, the average test of the fluids withdrawn gave successive strengths of 0.38, 0.28, 0.19, 0.11 and 0.07 per cent. This *shows the solution* to be practically inert as a bactericide and solvent after five minutes. Early withdrawals of the solution allow longer periods of negative pressure and opportunity for expansion of the lung. If pressure symptoms are too marked in a given case, at the expiration of five minutes the solution should be withdrawn, and the amounts injected should be decreased.

When the Dakin solution comes in contact with the cavity exudate, chloramins form which also have bactericidal properties (lasting thirty minutes to one hour—Dakin), and for this reason the solution is usually left in for several minutes.

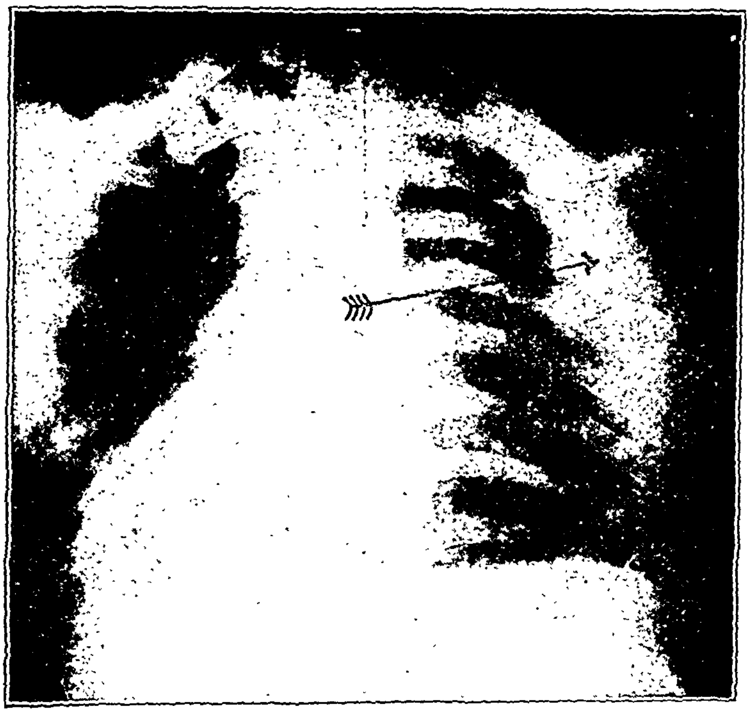

Fig. 4.—Same cavity obliterated by suction with bulb syringe (negative pressure); thickened visceral pleura indicated by arrow now pressed against thoracic wall and all air removed.

The original tube is *not usually removed* until the cavity is *obliterated by adhesions.* The dressing will *ordinarily last until the tube is ready* to be removed; and, as there is *no cumbersome* apparatus of bottles and tubing to manipulate, the attending surgeon needs only one nurse as *an assistant* in giving treatments.

The surgeon himself *should* give at least one treatment daily, and *take cultures and smears.* The other treatments may be given by a properly instructed nurse.

The cavity *should* be *filled* once daily to three-fourths its original capacity, to prevent the walling off at the border of the cavity of small pockets before the cavity is sterile; for, if such pockets are formed, convalescence is *prolonged and* secondary operations may be necessary.

The secretions in the cavity should be *agitated vigorously* by quick compression of the bulb so as to make a more homogeneous *emulsion before taking the culture* and smear. The assistant will handle the sterile test tubes and make the smears while the surgeon gives the treatment. It is important to note that the amount of negative pressure *obtained by the suction of the half-ounce* bulb syringe is considerable, as such a syringe will lift water to a height of 7 feet in a 6 mm. tube. Also roentgenograms taken just after such negative (suction) pressure has been made show large pleural cavities, even those of old standing, to be almost obliterated (Figs. 3 and 4). If at any time air is allowed to enter and cause the lung to collapse, full expansion is reestablished by this process. That the negative pressure is maintained within the chest wall after many hours is shown by the fact that when the tube fastened into the pleural cavity by this technic is connected with a tube leading from a bottle of Dakin's solution and clamp on the chest removed, the solution will be drawn into and fill the cavity.

After from one to seven days' treatment with Dakin's solution, given as described above, the pyogenic membrane will have been dissolved and the cavity made fairly sterile. The smears will show, on the average, one bacterium to ten fields, or may be entirely negative, and the cultures will *show a gradual diminution* in the number of colonies, though they *may* still be innumerable. Continuance of the Dakin *solution* would, in time, probably sterilize the cavity *completely*; but instead of continuing the Dakin *solution at this* stage, one should change to and inject a 2 per cent. dilution of liquor formaldehydi in glycerin, once or twice daily, for these reasons:

1. Cultures become sterile in from one to ten days, generally the second or third day.

2. As the solution of formaldehyd is a much stronger bactericide than the Dakin solution, there is less danger of pus pockets forming.

It is to be noted that with the use of Dakin's solution smears may be negative when cultures are positive. With formaldehyd solution the reverse is true; cultures are negative but smears may be positive. In other words, bacteria present under Dakin's solution treatment, while few in number, are viable; under formaldehyd treatment, they may be more numerous but are nonviable.

The formaldehyd solution is injected in amounts of from 3 to 40 c.c. daily and left in the cavity from twelve to twenty-four hours. Before each injection with formaldehyd solution the cavity is given one of the usual Dakin treatments. At first, the formaldehyd injection usually is followed in about four hours by a rise of temperature of from 1 to 3 degrees, a slight burning sensation in the cavity and, occasionally, pain in the shoulder and neck of the affected side and, at times, in the epigastrium. For this reason, it is not advisable to use the formaldehyd solution in acute cases until the usual course of treatment with Dakin's solution is given and the pneumonia, if present, has subsided.

The first injection in large cavities should not be more than 10 c.c. In twenty-four hours the cavity will usually contain from 20 to 120 c.c. of brownish fluid. This should be aspirated and the cavity filled two-thirds the original capacity with Dakin's solution left in for several minutes, aspirated, and the formaldehyd solution again injected. If the cavity is large, and the reaction not severe, 40 c.c. may be used. In two or three days, the fluid will become serosanguineous, and usually no colonies grow on cultures made on blood-agar plates. After the cultures are negative for three successive days, the amount of formaldehyd solution instilled daily should be reduced to from 3 to 10 c.c. and the maximum negative pressure maintained until the cavity has been reduced to a content of 50 c.c. or less.

The size of the cavity can be determined by injecting Dakin's solution and noting the resistance offered when pressing the bulb and the force of expulsion of the solution when the syringe is removed and the tube left open. Care must be taken not to break up new adhesions.

Under the treatment described above, adhesions soon form because of the thorough cleansing, irritation and rapid partial sterilization by the Dakin solution, followed by the complete sterilization by the formaldehyd solution, and the close contact of the parietal and visceral pleuras due to the long, constant negative pressure.

REPORT OF CASES

The following cases of the thirty-two treated by the closed method are reported as fairly typical:

CASE 1.—*Streptococcus hemolyticus infection, complicated by a bronchial communication. Attempt for two months to cure by repeated aspirations, but sterilization in six days by the closed method, with the use of Dakin's solution alone.*

A private, aged 29, admitted to Walter Reed General Hospital, May 20, from a base hospital, was diagnosed, April 4, as having lobar pneumonia, Type III.

May 21, the patient weighed 96 pounds, was anemic and nervous, had insomnia and anorexia, and could not lie down. He raised 250 c.c. of thick sputum daily. Roentgenoscopy revealed density in the left chest, lower lobe.

May 23, pleuracentesis at the fifth interspace, postaxillary line, yielded 300 c.c. of thick pus. Smear showed streptococcus; culture showed pure *Streptococcus hemolyticus.*

June 5, 350 c.c. of pus were aspirated at the seventh interspace, postaxillary line.

June 14, there was slight improvement; the cough was less.

June 20, the patient was coughing much at night and morning, was extremely nervous, and cried at times, saying he did not know why. Repeated sputum examination was negative for tubercle bacilli.

July 12, 150 c.c. of green pus were aspirated at the ninth interspace postaxillary line.

July 14, there had been no cough for the last two days, except when the patient lay down. He slept propped up in bed.

July 16, he weighed 102. The closed method of treatment was instituted; a stab puncture was made at the ninth interspace, postaxillary line, and 350 c.c. of greenish pus were aspirated through a small rubber tube. Culture showed pure *Streptococcus hemolyticus.* A communication of the cavity with a bronchus made impossible a negative pressure and prevented the injection of more than 175 c.c. of Dakin's solution, which amount was used as regular treatment.

July 23, the patient had walked about the ward and outside at will since the operation. He weighed 108 pounds. There was no cough, the patient was ravenous, he slept soundly, and lay in any position.

July 26, Dakin's solution was stopped. Smears and cultures had been negative for three days.

August 6, the tube was still in place. Smears and cultures had been negative, daily, for the past nineteen days. Communication was open. The injection of 10 c.c. of formaldehyd solution, daily, was begun.

August 10, the patient weighed 122 pounds. Communication was closed, and negative pressure maintained.

August 20, the tube was removed. No suture was made.

September 20, the wound had now been closed one month. The patient weighed 136 pounds, a gain of 34 pounds, and felt normal.

CASE 2.—A private, aged 24, admitted from a base hospital to Walter Reed General Hospital, July 19, was diagnosed as having lobar pneumonia, July 3. A diagnostic puncture yielded thick, greenish pus. Smear showed five bacteria to the field, and the Type II pneumococcus was later determined.

July 19, the closed method treatment was instituted. A trocar-cannula puncture was made, a tube introduced through the cannula, and 350 c.c. of pus removed. The usual Dakin treatments were given, and on the second day when 150 c.c. of Dakin's solution were injected, the patient showed bronchial communication. The amount was reduced to 125 c.c. each treatment, and on the fourth day, smear showed one bacterium to five fields. Cultures were taken daily, though the number of colonies gradually decreased; July 29, they were still innumerable. The formaldehyd solution was then used, and in two days cultures were negative and smear showed one bacterium to five fields.

July 31, the treatment could have been safely stopped, but was continued to reduce the size of the cavity and to determine also if the smears could not be made negative.

August 18, the smears were positive and culture was negative. The tube was removed.

September 20, the wound had been closed one month. The patient gained 24 pounds and was on furlough.

CASE 3.—A private, aged 23, admitted, August 28, to Walter Reed General Hospital from a base hospital, had been diagnosed, July 23, as having left lobar pneumonia. He weighed 130 pounds. The temperature was 99.8, pulse 100, and respiration 32. He had had little sleep the past week.

August 29, roentgenoscopy revealed an encapsulated empyema extending from the fourth to the tenth rib, posteriorly, on the left side. The closed method of treatment was instituted.

Following a diagnostic puncture, a trocar-cannula puncture was made, and 575 c.c. of thick green pus, containing three bacteria per field, were removed through a small rubber tube. The patient was treated with Dakin's solution for two days, and formaldehyd solution one day, and then the smear showed one bacterium in ten fields and culture was negative. Daily injection of 3 c.c. of formaldehyd solution was given and negative pressure maintained for five days longer, when the tube was removed.

October 3, the wound had been closed twenty-eight days. The patient returned from furlough, weighing 164 pounds. There was full expansion of the chest. The physical and roentgenographic findings were negative. There was a scar as if made by a small bullet.

CASES TREATED BY THE CLOSED METHOD

	Number
Cases treated by the closed method exclusively	11
Treated first by open thoracotomy, followed by the closed method	21
Total	32
Recovered and returned to duty	10
Convalescent and out of hospital on furlough	16
Still under treatment*	6
Died	0
Discharged for disability	0
Total	32

* *Three of the six cases still* under treatment are of but one week's duration and the patients are doing well. The other three are left overs from open thoracotomy treatment and are *now* being treated by the closed *method, superimposed on long antecedent open treatment.*

None of the patients have died, but it is recognized that this fortunate outcome cannot obtain in a larger series of cases.

That twenty-six of the thirty-two patients, 81+ per cent., have entirely recovered without secondary operation or crippling complications is submitted as justification for further trial of the method advocated.

In seven cases treated here, repeated needle aspirations were used. One patient was apparently cured and returned to duty; four patients, who had small cavities, are still under observation, slowly improving after long periods of convalescence. Two, having become gradually worse after repeated aspirations, were treated by the closed method and cured in a short time. Had the other five been treated by the writer's method, it is believed that cure would have been affected in less than one-fifth the time.

Twenty of the thirty-one cases were of long standing. These cases had received the usual large thoracotomy incision with resulting chronic sinuses and cavities varying in size from 60 to 700 c.c. capacity. With fifteen other cases, they had been treated with dichloramin-T, 5 per cent., in chlorcosane, in amounts of from 5 to 75 c.c. daily for six weeks, with very poor results. The empyemic cavities of this series of eighteen cases remained positive for organisms even under the most intensive treatment with Dakin's solution, but became sterile in from one to ten days with the combination treatment of Dakin's solution and formaldehyd solution by the closed method. In these cases, after failure to cure by treatment through the thoracotomy openings, the large drainage tubes were replaced by smaller ones sealed into the cavity, after which the cases were treated as if they were originally closed method cases. The small cavities were given two treatments daily with the Dakin solution, followed by the formaldehyd solution. In two of these cases, while the large wounds were closing, it was necessary to use a rubber dam about 3 inches square, fastened with a double layer of adhesive plaster in order to establish and maintain negative pressure. Five hundred c.c. of Dakin's solution were injected into the large pleural cavities at 9 a. m., 3 p. m. and 6 p. m., and left in for about forty-five minutes. Following the last treatment, 40 c.c. of the formaldehyd solution were injected and left in over night.

While, in treating empyema cases, roentgen-ray and bacteriologic facilities are to be preferred, they are not absolutely essential when the closed method is used. After treatment from one to six days with Dakin's solution, followed by a few days' treatment with the formaldehyd solution, if the secretion has become a clear, serosanguineous fluid, one can feel fairly assured that the cavity is surgically sterile, even though no smears or cultures are made.

COMPLICATIONS

In ten cases in the series treated, a communication existed between the empyemic cavity and a bronchus. We think this complication exists more often than is generally believed. These communications caused but little interference in giving treatment with Dakin's solution. The patient can detect when the solution enters a bronchus, and thereafter the injection was always stopped just before the solution reached an amount that would enter the bronchus. The formaldehyd solution, which was used in six of these cases, seemed to hasten the closure of this opening.

One patient developed spontaneous pneumothorax:

Case 4.—A private, aged 31, was first treated for five weeks by repeated needle aspirations. He became gradually worse, and a small stab wound was made and 800 c.c. of *Streptococcus hemolyticus* pus were aspirated through a rubber tube and the case thereafter treated by the closed method. Rapid recovery ensued. The patient gained 37 pounds in forty-eight days. *After the wound had been closed for three weeks,* without any warning, one night while the patient was in bed, *he developed a spontaneous pneumothorax. This could not* be satisfactorily explained, though it was thought probably due to rupture of a small peripheral abscess of the lung. The patient had a chill and cold sweat. The temperature was 105, pulse 150, and respiration 40. The anterior left chest up to the fourth rib, where no aspiration punctures had been made, was highly tympanitic, and the posterior side was very dull, owing to the compressed lung. *The patient lost 16* pounds in the week following, but regained this in ten days.

COMPARISON WITH OTHER METHODS

The closed method is to be compared with treatment by repeated aspirations and the open methods of thoracotomy, either intercostal, or by resection of a short length of one or two ribs.

The repeated aspiration method always means more or less pain and a long period of convalescence. While pressure symptoms may be relieved through evacuation of the pus, the cavity is seldom completely emptied, and the absorption of toxins continues.

Murphy was first, many years ago, to use a 2 per cent. dilution of liquor formaldehydi in glycerin in the pleural cavity, and modified the treatment by simple aspiration, as follows: He withdrew the pus through a needle, immediately injected the formaldehyd solution, and allowed it to remain for from one to four weeks. This process was repeated usually three or four times until the pus in the cavity became sterile and converted into a serosanguineous fluid. This, he asserted, would be absorbed in from three to twenty months, and the cavity obliterated.

The open method, whether by rib resection or intercostal thoracotomy, is always accompanied by much pain and discomfort. The profuse discharge necessitates a large and expensive dressing which requires changing from two to six times daily. When Dakin's solution is used to irrigate the cavity, large amounts of petrolatum gauze must necessarily be used to protect the skin from irritation. The open wound not only invites contamination but also allows the lung to collapse and not uncommonly causes death from shock. For this reason, some users of the open method advocate delayed operation with repeated needle aspirations to relieve pressure symptoms, and permit adhesions to form to prevent the lung from collapse when the cavity is opened. With the closed method, the aspirations and delay are not necessary.

Deaths from hemorrhage soon after thoracotomy operations have been reported, and no doubt this accident occurs more often than is reported or suspected. In prolonged drainage cases, a large drainage tube may wear through the periosteum and cause an erosion of the rib, producing pain or causing fatal hemorrhage from one of the intercostal vessels.

In thoracotomy cases, the resulting scar is large and unsightly. It is frequently adherent to the ribs, and if so, is always more or less painful.

In closed method cases, the scar is so small as to be almost imperceptible, and is freely movable as no adhesions exist between it and the underlying tissues.

When the open method is used, with resulting complete or partial collapse of a lung, and there exists a severe bronchial or pneumonic involvement of the opposite lung, the patient's respiratory area is so diminished that chances of recovery are extremely poor, whereas, by using the closed method, as there is no collapse of the lung, the chances of recovery are very good.

Though we have as yet treated no cases of double empyema by the closed method, there is every reason to believe that in double empyema the pleurae of both lungs can be treated at the same time, which is an impossibility with the open method, and with even a better chance of recovery than with the open method when but one pleura is involved

When the Carrel treatment is instituted through a large thoracotomy incision, and several Carrel tubes are inserted, there is more or less uncertainty as to their position. Those which go to the upper part of the cavity permit only a momentary flush of Dakin's solution at each treatment, and the reflux at once pours out through the incision, giving the solution opportunity to give up only a small part of its available chlorin. On the other hand, in the dependent part of the cavity, a "puddle" is formed which acts as a mechanical barrier, preventing the newly "instilled" Dakin's solution from reaching the infected pleura, and also acts as a diluent, thus in both ways defeating the very principle on which the antiseptic action of Dakin's solution is based, namely, that the solution must not be below 0.40 per cent. in available chlorin, to be an efficient bactericide.

In cases of multilocular cavities, walled off by firm adhesions and not connected by lacunae, the open operation is advised so as to break up the adhesions. The incision should then be sutured to fit a small tube and the cavity treated by the closed method.

It is possible that an open operation may be necessary in some cases of long standing when the lung is somewhat fixed in compression or bound down by firm adhesions; but even in these cases we are not sure but that persistent negative pressure by the closed method will, in time, overcome the trouble.

We believe, if the closed method of treating empyema in acute cases is carried out properly, that there will rarely be any necessity for the Schede, Eastlander or Delorme operations.

Recent experience in five cases has shown that sodium hypochlorite solution with an increased alkalinity and three times the amount of available chlorin which is in Dakin's solution can be used in empyemic cavities by the closed method, with perfect safety.

With such a wide margin in the strength of the hypochlorite solution that can be used in empyemic cavities, it is practicable for those who do not have the usual facilities for making Dakin's solution to purchase a concentrated hypochlorite solution and dilute to the proper strength before using. Liquor sodae chlorinatae (Labarraque's solution), which is an official U. S. P. product, containing 2.5 per cent. of available chlorin, is preferable. This solution is easily available and can be used in a dilution of one part to from three to five parts of distilled water.

While a hypochlorite solution is to be preferred, we believe that sterile physiologic sodium chlorid solution, weak iodin or potassium permanganate solutions would be very efficient in the few days' preliminary treatment of the empyemic cavity by the closed method *before* using the formaldehyd solution, but as yet have had no experience with any solutions other than the hypochlorite.

CONCLUSIONS

1. Early operation by the closed treatment method has the following advantages:

(*a*) It can be done without shock to the patient or collapse of the lung.

(*b*) It provides perfect evacuation and cleansing of the empyemic cavity.

(*c*) It prevents absorption of toxins.

(*d*) It prevents the lung, compressed by the exudate, from becoming fixed in compression.

2. Sterilization is more rapid by the closed than by the usual methods, as the antiseptics are held in contact with the infected surfaces until they have exerted their full bactericidal action.

3. Dakin's solution followed by a 2 per cent dilution of liquor formladehydi in glycerin is the most ideal antiseptic method of treating empyema.

4. Communication of an empyemic cavity with a bronchus is more common than is generally suspected. It is not a contraindication to the use of Dakin's solution and formaldehyd solution, and more readily closes when these are used.

5. Constant negative pressure gives the maximum expansion of the lung, and the irritating and cleansing action of sodium hypochlorite solution causes rapid obliteration of the cavity.

6. In uncomplicated cases of empyema, the patient need not be kept in bed.

7. Test smears are negative when cultures are positive when Dakin's solution is used and vice versa when formaldehyd-glycerin is employed.

8. Roentgenographic and bacteriologic laboratory facilities, while always to be preferred, are not absolutely essential in treating empyema by the closed method.

9. The closed method is productive of great economy of time, labor and dressing material.

10. Treatment by the closed method can effect cures in many cases similar to those that are usually treated by the Schede, Eastlander or Delorme operation.

11. The closed method is practicable in the home and in country practice.

12. A hypochlorite solution of increased strength over Dakin's solution in both alkalinity and amount of available chlorin can be used in empyemic cavities with safety.

13. Labarraque's solution, diluted to the strength indicated, can be substituted for Dakin's solution.

14. The closed method offers good chances of effecting cures in cases of double empyema, through the possibility of treating the empyemic cavities on both sides at the same time, which treatment is impossible by the open method.

Walter Reed General Hospital.

INFLUENZA

REPORT OF A SPECIAL COMMITTEE OF THE AMERICAN PUBLIC HEALTH ASSOCIATION

[Note.—*To afford such aid as may be possible to administrative health officials, a committee of the American Public Health Association, consisting of Drs. W. A. Evans, Chicago, chairman; D. B. Armstrong, Framingham, Mass.; William H. Davis, Washington, D. C.; Mr. E. W. Kopf, New York, and Dr. William C. Woodward, Boston, was charged with the duty of preparing a provisional working formula, based on the facts and opinions presented at the meeting of the association in Chicago, Dec. 9 to 12, 1918. Because of the timely and important character of the subject, the report is published in full.*—Ed.]

NATURE OF THE EPIDEMIC

The present epidemic is the result of a disease of extreme communicability. So far as information available to the committee shows, the disease is limited to human beings.

The micro-organism or virus primarily responsible for this disease has not yet been identified. There is, however, no reason whatsoever for doubting that such an agency is responsible for it. Mental conditions may cause a person to believe he has influenza when he has not, and may make the patient who has the disease suffer more severely than he otherwise would. No mental state alone, however, will cause the disease in one who is not infected by the organism or virus that underlies the malady.

While the prevailing disease is generally known as influenza, and while it will be so referred to in this statement, it has not yet been satisfactorily established that it is the identical disease heretofore known by that name, nor has it been definitely established that all preceding outbreaks of disease styled at the time "influenza" have been outbreaks of one and the same malady.

There is no known laboratory method by which an attack of influenza can be differentiated from an ordinary cold or bronchitis or other inflammation of the mucous membranes of the nose, pharynx or throat.

There is no known laboratory method by which it can be determined when a person who has suffered from influenza ceases to be capable of transmitting the disease to others.

Laboratories are necessary agencies for the supervision and ultimate control of the disease. The research laboratory is necessary for the discovery of the causative micro-organism or virus, and for the discovery of some practicable method for the propagation of a specific vaccine and a curative serum. Clinical laboratories are necessary for the supervision and control of such vaccines and serums as may be used from time to time for the prevention of the disease and for therapeutic purposes, and for the information such laboratories can give to health officers and physicians as to such variations in the types of infective micro-organisms as occur during the progress of an epidemic.

Deaths resulting from influenza are commonly due to pneumonias resulting from an invasion of the lungs by one or more forms of streptococci, or by one or more forms of pneumococci, or by the so-called influenza bacillus, or bacillus of Pfeiffer. This invasion is apparently secondary to the initial attack.

Evidence seems conclusive that the infective micro-organism or virus of influenza is given off from the nose and mouth of infected persons. It seems equally conclusive that it is taken in through the mouth or nose of the person who contracts the disease, and in no other way, except as a bare possibility through the eyes, by way of the conjunctivae or tear ducts.

PREVENTION

If it be admitted that influenza is spread solely through discharges from the noses and throats of infected persons finding their way into the noses and throats of other persons susceptible to the disease, then no matter what the causative organism or virus may ultimately be determined to be, preventive action logically follows the principles named below and, therefore, it is not necessary to wait for the discovery of the specific micro-organism or virus before taking such action.

I. Break the channels of communication by which the infective agent passes from one person to another.

II. Render persons exposed to infection immune, or at least more resistant, by the use of vaccines.

III. Increase the natural resistance of persons exposed to the disease, by augmented healthfulness.

I. *Breaking the Channel of Communication.*—

(*a*) By preventing droplet infection. The evidence offered indicates that this is of prime importance.

(*b*) By sputum control. The evidence offered indicates that the danger here is due chiefly to contamination of the hands and common eating and drinking utensils.

(*c*) By supervision of food and drink. Evidence offered does not indicate much danger of infection through these channels.

Details and practical methods possible for the limitation of infection through droplets, sputum, and food and drink are discussed later under special preventive methods.

II. *Immunization and Vaccines.*—(These are discussed in a report of the laboratory committee farther on.) In the present epidemic vaccines have been used to accomplish:

1. The prevention or mitigation of influenza per se.
2. The prevention or mitigation of complications recognized as due to the influenza bacillus or to various strains of streptococci and pneumococci.

In relation to the use of vaccines for the prevention of influenza, the evidence that has come to the attention of the committee as to the success or lack of success of the practice is contradictory and irreconcilable. In view of the fact that the causative organism is unknown, there is no scientific basis for the use of any particular vaccine against the primary disease. If used, any vaccine must be employed on the chance that it bears a relation to the unknown organism causing the disease.

The use of vaccines for the complicating infections rests on more logical grounds, and yet the committee has not sufficient evidence to indicate that they can be used with any confident assurance of success. In the use of these vaccines the patient should realize that the practice is still in a developmental stage.

The committee believes that when vaccines are used experimentally for the purpose of determining their preventive or curative value, the following conditions should be complied with:

1. The groups of vaccinated and unvaccinated persons should be the same in number.
2. The relative susceptibilities of the two groups should be equal, as measured by age and sex distribution, previous exposures to infection without development of influenza, and a previous history as to recent attacks of the disease.
3. The degree of exposure in each group should be practically the same in duration and intensity.
4. The groups should be exposed concurrently during the same stage of the epidemic curve.

III. *Increased Natural Resistance of Persons Exposed to Infection.*—Physical and nervous exhaustion should be avoided by paying due regard to rest, exercise, physical and mental labor, and hours of sleep. The evidence is conclusive, however, that youth and bodily vigor do not guarantee immunity to the disease.

The nature of the preventive measures practicable and necessary in any given community depends in a large part on the nature of the community itself, as to population characteristics, industries, and so on, and on the stage and type of the epidemic curve. For example, the measures to be adopted in a purely rural community would not be practicable or desirable in a large metropolitan area, nor would the measures desirable and feasible at the beginning or end of an epidemic be found those best adapted for the intervening period. The committee has found it impossible, therefore, to lay down any rules for the guidance of all health officials alike in preventive measures. The most it has been able to do has been to state certain general principles that in its judgment should underlie administrative measures for the prevention of influenza. The application of these principles to the needs of any particular community must be left for determination by the officers of that community who are responsible for the protection of its public health.

The preventive measures recommended by the committee are as follows:

A. Efficient organization to meet the emergency, providing for a centralized coordination and control of all resources.

B. Machinery for ascertaining all facts regarding the epidemic:

1. Compulsory reporting.
2. A lay or professional canvass for cases, etc.

C. Widespread publicity and education with respect to respiratory hygiene, covering such facts as the dangers from coughing, sneezing, spitting, and the careless disposal of nasal discharges; the advisability of keeping the fingers and foreign bodies out of the mouth and nose; the necessity of hand-washing before eating; the dangers from exchanging handkerchiefs; and the advantages of fresh air and general hygiene. Warnings should be given regarding the danger of the common cold, and possibly colds should be made reportable so as to permit the sending of follow-up literature to persons suffering from them. The public should be made acquainted with the danger of possible carriers among both the sick and the well and the resultant necessity for the exercise of unusual care on the part of everybody with respect to the dangers of mouth and nasal discharges.

D. Administrative procedures:

1. There should be laws against the use of common cups, and improperly washed glasses at soda fountains and other public drinking places, which laws should be enforced.
2. There should be proper ventilation laws, which laws should be enforced.

Since the disease is probably largely a group or crowd problem, the three following subheads are especially important:

3. *The Closing of Meeting Places.*—Since the spread of influenza is recognized as due to the transmission of mouth and nasal discharges from persons infected with influenza, some of whom may be aware of their condition but others unaware of it, to the mouths and noses of other persons, gatherings of all kinds must be looked on as potential agencies for the transmission of the disease. The limitation of gatherings with respect to size and frequency, and the regulation of the conditions under which they may be held must be regarded, therefore, as an essential administrative procedure.

Nonessential gatherings should be prohibited. Necessary gatherings should be held under such conditions as will insure the greatest possible amount of floor space to each individual present, and a maximum of fresh air, and precautions should be taken to prevent unguarded sneezing, coughing, cheering, etc.

Where the necessary activities of the population, such as the performance of daily work and the earning of a living, compel considerable crowding and contact, but little is gained by closing certain types of meeting places. If, on the other hand, the community can function without much contact between the individual members, relatively much is gained by closing or preventing assemblages.

Schools: As to the closing of schools, there are many questions to be considered.

(*a*) Theoretically, schools increase the number and degree of contacts between children. If the schools are closed, many of the contacts which the children will make are likely to be outdoors. Whether or not closing will decrease or increase contacts must be determined locally. Obviously, rural and urban conditions differ radically in this regard.

(*b*) Are the children in coming to and going from school exposed to inclement weather or long rides in overcrowded cars?

(*c*) Is there an adequate nursing and inspection system in the schools?

(*d*) Is it likely that teachers, physicians and nurses can really identify and segregate the infected schoolchild before it has an opportunity to make a number of contacts in halls, yards, rooms, etc.? We suggest that children suspected of having influenza and held in school buildings for inspection should be provided with and required to wear face masks.

(*e*) Will the closing of schools release personnel or facilities to aid in fighting the epidemic?

(*f*) If schools are kept open, will the absence of many teachers lower the educational standards?

(*g*) If a number of pupils stay at home because of illness or fear, will they not constitute a heavy drag on their classes when they return?

(*h*) If schools are closed, is there likely to be an outbreak in any case when they are reopened?

Churches: If churches are to remain open, services should be reduced to the lowest number consistent with the adequate discharge of necessary religious offices, and such services as are held should be conducted in such a way as to reduce to a minimum the intimacy and frequency of personal contact.

Theaters: As regards theaters, movies, and meetings for amusement in general, it seems unwise to rely solely or in great part on the ejection of careless coughers. In the first place it is difficult to determine who is a careless cougher, and after each cough, danger has already resulted. It seems, too, that the closing of theaters may have as much educational value as their use for direct educational purposes, etc. Discrimination as to closing among theaters, movies, etc., on the basis of efficiency of ventilation and general sanitation may be feasible.

Saloons, etc.: The closing of saloons and other drinking places should be decided on the basis of the probability of spread of the disease through drinking utensils and the conditions of crowding.

Dance Halls, etc.: The closing of dance halls, bowling rooms, billiard parlors and slot-machine parlors, etc., should be made effective in all cases where their operation causes considerable personal contact and crowding.

Street Cars, etc.: Ventilation and cleanliness should be insisted on in all transportation facilities. Overcrowding should be discouraged. A staggering of opening and closing hours in stores and factories to prevent overcrowding of transportation facilities may be cautiously experimented with. In small communities where it is feasible for persons to walk to their work it is better to discontinue the service of local transportation facilities.

Funerals: Public funerals and accessory funeral functions should be prohibited, being unnecessary assemblies in limited quarters, increasing contacts and possible sources of infection.

4. *Masks.*—The wearing of proper masks in a proper manner should be made compulsory in hospitals and for all who are directly exposed to infection. It should be made compulsory for barbers, dentists, etc. The evidence before the committee as to beneficial results consequent on the enforced wearing of masks by the entire population at all times was contradictory, and it has not encouraged the committee to suggest the general adoption of the practice. Persons who desire to wear masks, however, in their own interests, should be instructed as to how to make and wear proper masks, and encouraged to do so.

5. *Isolation.*—The isolation of patients suffering from influenza should be practiced. In cases of unreasonable carelessness, it should be legally enforced most rigidly.

6. *Placarding.*—In cases of unreasonable carelessness and disregard of the public interests, placarding should be enforced.

7. *Hospitalization.*—The theory of complete hospitalization is that, if all the sick were hospitalized, the disease would be controlled. In certain somewhat small communities where hospitalization of all cases was promptly inaugurated, the disease did come quickly under control. It must be recognized, however, that unless every infective person can be detected and identified as such and removed to the hospital before he has infected others, hospitalization cannot be depended on to eliminate the disease.

In general, home treatment is to be advocated where medical, nursing and other necessary facilities are adequate, and where home treatment is not directly contraindicated by the danger of infecting others. The hospitalization in any case, mild or severe, should be undertaken only when facilities for home treatment are inadequate with respect to medical and nursing care or otherwise. The objection to routine hospitalization of mild cases lies in the fact that patients not already suffering from secondary infections may acquire them by exposure to hospital cases already so infected. The objection to the routine hospitalization of severe cases lies in the danger to the patient necessarily incident in the transfer from home to the hospital.

8. *Coughing and Sneezing.*—Laws regulating coughing and sneezing seem to be desirable for educational and practical results.

9. *Terminal Disinfection.*—Terminal disinfection for influenza has no advantage over cleaning, sunning and airing.

10. *Alcohol.*—The use of alcohol serves no preventive purpose.

11. *Sprays and Gargles.*—Sprays and gargles do not protect the nose and throat from infection, for the following reasons:

(*a*) So far as the knowledge of the committee extends, no germicide strong enough to destroy infective organisms can be applied to the nose and throat without at the same time injuring the mucous membranes.

(*b*) Irrigation of the nose and throat to accomplish the complete mechanical removal of the infective organism is impracticable.

(*c*) Their use tends to remove the protective mucus, to spread the infection and to increase the liability of actual entrance of the infective organisms.

(*d*) Their domestic use is liable to lead in families to a common employment of the same utensils.

(*e*) The futility of sprays and gargles has been demonstrated with respect to certain known organisms, such as the diphtheria bacillus and the meningococcus.

MISCELLANEOUS CONSIDERATIONS

1. Colleges, asylums and similar establishments may with advantage enforce rigid institutional quarantine against the outside world, if they begin in the early stage of an epidemic, provided they are so located and conducted as to render the procedure reasonably likely to be effective, even temporarily; for even temporary success will postpone the appearance of the disease, if it appears at all, to a time when the patients will be more likely to be able to have adequate medical and nursing care.

2. The recommended measures for control, even if they do not accomplish the desired end, should at least be instrumental in distributing the epidemic over a longer period of time, which in itself is highly desirable.

The statistics of the disease and the keeping of proper records are extremely important. The lack of knowledge regarding innumerable factors in reference to the disease makes all the more desirable complete case records, etc.

4. The committee wishes to emphasize the need for the complete statistical study of the collected data on the mortality, morbidity, case fatality, duration, economic aspects, and therapeutics of the disease. Through the collection of the facts in a uniform manner, and through the analysis of such tabulated data, especially mathematical graduation, and testing and study of the figures, important contributions to the natural history and typical characters of the disease may be expected. General principles as to the etiology,

fatality and practical management of influenza may follow from the extensive survey of the epidemic in the statistical laboratory as well as from the intensive bedside observation of single cases of the disease.

5. The measures recommended are calculated to be effective in the promotion of respiratory hygiene in general and particularly in the control of pneumonia and other respiratory infections.

ADMINISTRATIVE MEASURES FOR RELIEF

The committee on administrative measures for relief would submit the following considerations as constituting a summary of the important measures for meeting epidemic conditions:

I. *General Rules.*—1. Reporting should be made compulsory.

2. Isolation, by cooperation and education, should be practiced to a point where it does not diminish the willingness of the physician to report.

3. Placarding would seem to be subject to the same limitations as is isolation.

4. The closing of schools, prohibition of funerals, etc., being preventive measures, are not touched on in this report, except to mention that the closing of many agencies will release medical, nursing and volunteer services for special influenza work.

5. It may be necessary to grant authority and power to the health authorities to administer relief.

II. *Preliminary Measures.*—1. The listing and distribution of resources, including physicians, nurses, social workers, nurses' aids, clerks, domestics, laundresses, automobiles, chauffeurs, mask makers and volunteers of all kinds should be undertaken.

All available publicity channels should be used to promote volunteer service.

An appeal should be made for voluntary donors of human blood serum from convalescent influenza patients, to be held in readiness for use in treatment.

2. Resources should be centralized under one control, with central and branch headquarters, the city being districted for medical, nursing and other work.

The central headquarters should be ordinarily under the supervision of a board representative of the most important agencies concerned, the board's work to be administered through a manager (presumably the health officer) selected for his fitness.

3. The service should be maintained on a twenty-four hour basis, and a system of outgoing and incoming telephone service is essential.

4. The local authorities should get and keep in touch with state and national agencies.

III. *Current and Continuous Analysis of Case Situation.*—In the smaller communities a canvass should be made of all physicians, soliciting information as follows:

(*a*) Number of cases under care.
(*b*) Number of cases needing hospital treatment.
(*c*) Number of cases needing home nursing care.
(*d*) Number of cases requesting medical service but not reached.

This information will indicate the situation as regards the need for emergency nursing and medical service, and should be acquired as fully as possible in larger communities, through various agencies, such as a current lay or police canvass of homes, etc. The continuous classification of cases according to these groupings is of practical value.

IV. *Analysis, Augmentation and Organization of Principal Facilities.*—(A) Field Nursing: 1. Ordinarily nursing facilities utilized in general public health work should be diverted to meet the epidemic situation, and should be used on a district basis, with all other available facilities, under one supervision.

2. Nursing assistants, volunteers and the like should be used whenever possible in homes and institutions, under expert supervision, after classification and assignment on a basis of minimum standards as to fitness, and such intensive training in the care of influenza and pneumonia patients as may be feasible.

3. From the standpoint of the patient, home treatment is to be advocated, if medical, nursing, disease prevention and other facilities are adequate.

4. Restriction so far as possible through the pressure of public opinion should be brought against the unnecessary use of private nurses.

5. Automobile transportation should be provided, and the nursing service used to encourage isolation and education.

6. Special record forms are essential for this and the medical work, and a special subcommittee is proposed to meet this problem.

7. Provision as to housing and care should be made for out of town nurses.

8. We recommend further training with reference to influenza for all graduates of Red Cross home nursing courses and more extensive use of their services. This would necessitate frequent and careful registration (names, addresses and telephone numbers) and further information regarding personal health, age and ability and willingness to serve.

(B) Emergency Medical Service: 1. The medical service should be handled through the central office, the physicians being responsible to the central office, though perhaps assigned to district offices.

2. In this emergency service there should be utilized all available physicians, such as school and factory physicians, volunteers, practitioners on a paid basis, and fourth year medical students. This service should cover all calls reported as unreached by private physicians or received through other channels, and should be coordinated with the special nursing service, being provided with automobile transportation, machines being hired if necessary.

3. The emergency medical service should be used to select cases needing hospital care.

4. It may be feasible to institute a central clearing house in certain districts for private physicians' calls.

5. An arrangement should be made through the medical licensing board for the granting of temporary permits to practice to reputable physicians from out of the state, at the request of the Central Influenza Committee.

6. In some localities it may be feasible to district the local practitioner and to have him meet special calls on a part time basis for adequate compensation.

7. Certain of the relatively nonessential specialties should be discouraged and the physicians in those specialties urged to volunteer for emergency district work. This type of service may be operated on a pay or free basis.

8. Presumably some effort should be made, through an authoritative medical commission, to suggest standard methods of treatment and wise limitations as to therapeutic procedure.

(C) Hospital Facilities: 1. It is essential that the facilities, if possible, be kept ahead of the demand. A daily canvass should be made and data collected regarding available beds, medical and nursing needs, domestics, food, cots, supplies, etc. A regular visit by an inspector will probably prove more effective than an attempt at telephone communication.

2. Under most conditions a central clearing house, covering most if not all of the hospitals, is advisable for the admission of cases. Through this channel the severer cases may receive first consideration. Owing to constant changes in the hospital bed situation, the daily canvass of facilities may not be wholly depended on; on the contrary, it may usually be necessary to telephone the hospital in order to make sure regarding the admission of a particular case. In any event the hospitals, if facilities are inadequate, should be impressed with the necessity for admitting only the most severe or needy cases, pay or free. Special hospital arrangements should be provided for pregnant women.

3. It is advisable to add wards or tents or new equipment to existing institutions rather to establish entirely new emergency hospitals. If practicable, certain hospitals may be urged to handle influenza cases exclusively.

4. Nonemergency surgical and chronic medical cases amenable to home treatment should be dehospitalized.

5. A convalescent home, if adjacent to the hospital, may serve for the care of mild and convalescent cases, thereby increasing the space in the hospital for acute cases, obviously involving an increase in the nursing facilities.

6. A canvass of ambulance facilities should be made, ambulances being requisitioned with payment, or hired by contract, if necessary. Automobiles and motor trucks should be potentially mobilized for this purpose. Frequently military equipment may be used if accessible.

V. Social and Relief Measures: 1. The central office should keep the family advised regarding the patient, thereby saving telephone calls, trolley fares and worry on the part of the family, and thereby increasing the willingness for hospitalization.

2. Volunteer workers, such as Red Cross volunteers, teachers and relatives, should be placed in care of families in which the responsible members are dead or hospitalized, this service being under expert social supervision, and the families in touch with the supply system. Supervision of placed-out children is also necessary.

3. Homes should be investigated before patients are discharged into them, when destitution or other untoward circumstances are apparent.

4. Precaution should be taken that institutions and families too busy with the influenza situation to look after their own needs are covered by the general relief measures.

5. Ordinary charitable relief should be handled through the routine agencies, and the service coordinated with the other epidemiologic measures. Churches, lodges, etc., should be urged to handle their own cases, in order to relieve the pressure on the central agency. Aid should be immediate, without protracted investigation.

6. Recreation facilities (motoring, etc.) should be provided for the physicians and nurses while off duty.

VI. Food: 1. Available central cooking facilities should be used so far as is necessary, such as the dietetic equipment in high schools, normal schools, colleges, etc., with a delivery system to families and institutions in need.

2. Individual families should be encouraged to cook additional amounts, these to be delivered to central diet kitchens for distribution, a standard list of prepared foods needed being devised and advertised, with recognition of racial customs and preferences.

3. It may be necessary to establish canteens in sections of the city.

VII. Laundry: 1. A special collection and distribution system may be essential both for homes and for institutions.

2. It may be necessary to take over a public laundry with compensation, or a private nonmedical institution laundry.

VIII. Provision for Fatalities: 1. Death reporting should be prompt (twenty-four hours) and a record kept so as to insure prompt disposal of bodies.

2. A daily canvass of available coffins should be made, labor assured for construction, and possibly no coffins sold without the permit of the influenza administration office.

3. If morgue facilities are inadequate, a central place should be provided, with embalming facilities, for the temporary disposal of bodies.

4. A canvass of hearses should be made and regulations issued prohibiting unnecessarily long hauls, insisting on maximum loads, etc. A central control will prevent unnecessary duplication as to routes, etc.

5. A reserve supply of trucks and automobiles should be at hand for use in various ways in connection with the handling of fatal cases.

6. The number of graves required should be estimated and labor released from public works or secured through other channels (possibly military) for digging. Possibly temporary trench interment may be necessary.

IX. Education, Instruction and Publicity: Literature and special instructions will be necessary on many phases, including the following:

1. Instructions to physicians as to reporting, facilities available, district arrangements, etc.

2. Advice to physicians regarding treatment standards and suggestions.

3. Instructions for families, to be distributed by nurses, physicians, social workers, druggists and others covering the problems of care during the physician's absence.

4. Instructions to the public as to where aid may be secured, to be printed in various languages, and distributed by druggists, displayed in street cars, used in the press, etc.

5. Instructions for families on "What to do till the doctor comes."

6. Instructions to physicians, factory managers, school superintendents and others, urging the necessity for immediate home and bed treatment at the first sign of respiratory disease.

7. Popular literature on the essentials of adequate care, the danger of returning to work too soon, etc. Popular press space is worth paying for, if it cannot be secured otherwise.

8. Popular publicity as to legitimate medical, nursing, undertaker, drug and other charges, to prevent profiteering.

X. Miscellaneous: 1. The cooperation of pharmaceutic agencies should be secured to insure an adequate supply of drugs and druggists.

2. Influenza victims and their families should have "first call" on fuel deliveries.

3. While follow up procedures are not legitimately a factor in the epidemic situation, their consideration is essential to an adequate meeting of the entire problem. This means adequate provision for medical examination and nursing care, relief measures, industrial employment problems, and the follow up of special sequelae, such as cardiac affections and tuberculosis.

4. It is finally suggested that the health department draw up a program based on the foregoing outline, holding it in reserve for future use, if not immediately needed, and modifying the proposal to fit the size and other characteristics of the particular community.

THE BACTERIOLOGY OF THE 1918 EPIDEMIC OF SO-CALLED INFLUENZA

The epidemic disease known as influenza is believed to be due to an undetermined organism which causes an infection that lowers the resistance of the body as a whole, and of the respiratory organs in particular. This allows the invasion of other pathogenic micro-organisms. The most important complicating infections are due to the influenza bacilli, different strains of pneumococci and different varieties of streptococci. Some careful observers regard certain of these organisms as the primary cause.

In each case, one or several of these micro-organisms may be present. In different portions of the country the dominating variety of organism has been found to differ.

VACCINES

Assuming that the cause of the epidemic is an unknown virus, it does not seem possible at present to prevent the primary disease by vaccination with known organisms. Against the secondary infections there would seem to be a theoretical basis for the use of vaccines, and especially for the use of vaccines prepared from organisms responsibe for complications which may differ in various localities at various times. This variable bacterial flora may militate against the practical application of vaccination on a large scale, because it would seem to require frequently repeated vaccinations with the flora that may be encountered. It is impossible at present to evaluate the reports from the use of these vaccines adjusted to meet local conditions. More data obtained under carefully controlled conditions are needed.

Stock vaccines made from the influenza bacillus alone or from other bacteria have been used to a considerable extent. The injections of stock vaccines have seemed to mitigate to some degree some outbreaks of influenza, and also the severity of the complicating infections; but in those instances in which the results of the use of vaccine have been controlled, no appreciable results have been obtained. The fact that the vaccine is usually employed after the epidemic has broken out and is perhaps on a decline, and the fact that an unknown number of people have been exposed, make it very difficult to draw conclusions as to its efficacy.

RECOMMENDATIONS

Your committee recommends that until such time as the efficacy, or the lack of efficacy, of prophylactic vaccination against influenza is established, vaccine, if used, should be employed in a controlled manner, under conditions that will allow a fair comparison of the number of cases and of deaths among the vaccinated and nonvaccinated groups. Particular attention should be directed to securing data as to the period in the epidemic at which vaccinated and nonvaccinated persons developed the disease.

Your committee is of the opinion that the indiscriminate use of stock vaccines against influenza and influenza with pneumonia cannot be recommended.

Nothing in these recommendations should be interpreted as discouraging the use of a pneumococcus stock vaccine against lobar pneumonia.

This epidemic emphasizes the importance of properly equipped laboratories.

HISTORY AND STATISTICS OF THE EPIDEMIC

Your subcommittee wishes to say that in view of the fact that the historical and other data of the epidemic are still in process of collection, no positive statement can be made at the present time on the precise incidence of the disease in the American population. On the basis of the best data available, your subcommittee estimates that there were not less than 400,000 deaths from the disease in the United States during the months of September, October and November, 1918. The major portion of this mortality occurred between the ages of 20 and 40, when human life is of the highest economic importance. We would suggest that this subcommittee be authorized to cooperate with the special committee on statistical study of the epidemic of the section on vital statistics of this association, and that the data collected through the latter special committee be reported through the subcommittee on history and statistics of the epidemic to the general reference committee on the influenza epidemic. Standard forms for purposes of statistical tabulation, analysis and graphic presentation will be submitted in a supplementary report at an early date.

SUGGESTIONS

In view of the probability of recurrences of the disease from time to time during the coming year, health departments are advised to be ready in advance with plans for prevention, which plans shall embody the framework of necessary measures and as much detail as is possible. Laws plainly necessary should be enacted and rules passed now. Emergency funds should be held in reserve or placed in special appropriations, which appropriations can be quickly made available for influenza prevention work.

The probability that as an after-effect of the influenza epidemic there will be an unusually high pneumonia rate for several years should be taken into consideration.

Of measures for the control of the disease, bacteriologic studies as to the nature of the organisms causing the primary infection and as to bacteria associations, new and improved procedures leading to the production and use of effective vaccines and curative serums, and the fresh air treatment of the infected appear to offer most promise.

Catalase and Oxidation.—W. E. Burge reports in *Science*, Aug. 16, 1918, that as the result of investigations in the physiologic laboratory of the University of Illinois, it is determined that physical work and the ingestion of food increase oxidation in the body by stimulating the liver to an increased output of catalase.

SATURDAY, DECEMBER 21, 1918

A GENTLE REMINDER

A blue slip to be used in remitting subscriptions and dues for Fellowship in the American Medical Association for 1919 is inserted in The Journal this week. Last week we explained its use under the heading "Practical Economy." The use of this slip by Fellows and subscribers will result in a considerable saving on the cost of sending the customary bills. Over 20,000 subscribers utilized the slip last year, and it is hoped that an even greater number will use it this year. Don't delay! It's the little things in life that count.

FACT AND OPINION ON THE PRESENT EPIDEMIC OF RESPIRATORY DISEASE

The recent meeting of the American Public Health Association in Chicago was devoted largely to the present epidemic of influenza. An abstract of the proceedings of the sessions devoted to this subject appears in this issue of The Journal. This abstract is not, of course, a verbatim report of the proceedings, but represents that which seems of permanent value, eliminating a large mass of discussion that was argumentative rather than of the nature of scientific evidence. There are certain large phases of the subject on which much evidence was presented leading to what might be expressed as a consensus of opinion. It must be borne in mind that this organization consists primarily of public health officials, though it includes many research workers and physicians engaged in medical practice and investigation.

The discussions relative to the etiology of the present epidemic resolve themselves into the belief that the bacillus of influenza is not the primary etiologic factor, and that the actual cause is as yet unknown. As indicated by present evidence, a coccus, perhaps a pneumococcus of Type IV, or the coccus described by Mathers and others as a green-producing streptococcus, or the diplostreptococcus described by numerous investigators abroad, seems to have impressed many as of importance in causing death. It seems reasonable to suspect that perhaps these observations all may refer to the same organism or to closely related organisms; but sufficient work has not yet been done with this organism to prove a definite etiologic relation to the epidemic. The reports, however, indicate that such organisms are found in a large majority of the cases of the disease, especially in those resulting fatally, and that if they are not the primary etiologic factors, they seem to bear a definite relationship to the complicating pneumonia and the resulting mortality.

A second point of elaborate discussion in the proceedings concerned the use of the face mask as a means of prevention. Arguments were made for and against the use of this mask. Most of those who took part in the discussion seemed to lose sight of the fact that definite evidence has been presented to show that the wearing of a face mask prevents the diffusion of *pathogenic organisms of which we have definite knowledge*. If a person coughs toward a plate of medium exposed at a certain distance from the mouth and nose, a large number of colonies of bacteria develop on the plate. If the same person provides himself with an adequate face mask and coughs toward the plate, the organisms do not appear and grow on the plate. This is a simple experiment which any investigator may easily demonstrate for himself. The organisms found on the plates are, in many cases, bacteria similar to those found in the lungs of persons dying in the present epidemic. There is reason to believe that a face mask properly worn will aid in the prevention of infection from these organisms. There is also evidence to the effect that face masks, properly worn and controlled, have prevented the spread of the epidemic in certain institutions, whereas it spread rapidly in other institutions where the face mask was not worn. While not conclusive, this evidence leads to the opinion that, properly used, the face mask has value in the prophylaxis of influenza. Whether or not it is worth while to attempt to mask entire communities, either small villages of a few hundred or a few thousand inhabitants or large municipalities, such as San Francisco, compelling all of the persons in the municipality to wear the mask in public over an extended period of time, there is grave doubt as to whether this procedure can be sufficiently controlled to make it of practical value. Not that the public does not cooperate fully with the health department in its effort, but that the efficiency of the cooperation cannot be made sufficiently perfect.

Incidentally, a paper presented by Lieutenant-Colonel Cummings of Newport News, Va., indicated to the satisfaction of most listeners that a significant factor in the spread of infection in Army camps was the inadequate washing of mess kits. Cummings was strongly imbued with the belief that hand to mouth infection was more important than mouth to mouth or, rather, face to face, infection. It was his belief that a special value attaches to the face mask in aiding in the prevention of hand to mouth infection.

Another greatly debated point concerned the use of prophylactic vaccines. As we have stated before, these vaccines are at present of two main types. One is a vaccine composed of various strains of the influenza bacillus, the other a mixed vaccine containing the various types of pneumococci, also streptococci, influenza bacilli and staphylococci. Both types have been given extensive trial, unfortunately, however, except in a few cases, without adequate scientific control. The indiscriminate vaccination of the population, vaccinating those who come and not vaccinating others, without keeping adequate records of both, can hardly yield evidence worthy of consideration for or against the use of vaccines as a prophylactic measure. We recently[1] pointed out that the use of the vaccines was wholly in the experimental stage. Since that time reports have appeared of definite, adequately controlled experiments with each of these vaccines. These indicate that this use is at best still in the experimental stage, and that these vaccines are probably not efficacious in the prophylaxis of influenza. It is well to repeat here that the question as to whether or not these vaccines are efficacious cannot be settled by argument as to the theory of their use or by statement of opinion. The question is one that is susceptible of scientific proof.

SCURVY AND CONSTIPATION

In view of the departures from the customary character of the diet that are impending or already in operation to a large extent among the civil population, as well as among the armies of the world, it is fortunate that scurvy has again become the subject of extensive scientific investigation. This disease is admittedly associated with alterations in the diet, and commonly has manifested itself prominently when certain extensive changes in the usual rations have been necessitated by force of altered food conditions. We have recently referred to some of the conflicting views regarding scurvy, particularly as they are elucidated by modern experience with antiscorbutic methods.[2] The symposium on diseases due to deficiencies in nutrition—an important feature of the session of the American Medical Association last June—helped to secure the formulation of the debated points of view.[3]

We must revert here to the theory of McCollum, which has been widely quoted of late. As he was unable to maintain guinea-pigs—the classic animal for the study of experimental scurvy—in health on a diet of oats and milk, from which he asserts that nothing is lacking for the adequate nutrition of rats and swine, McCollum believes that the physical texture rather than the chemical make-up of the scorbutic diet must be at fault. As he develops his view, the guinea-pig ordinarily thrives only on diets that contain a succulent vegetable, since its cecum becomes packed with feces on diets that are unsuited to its digestive tract. The cecum in this species is very large and delicate, and such a constipating diet as oats and milk causes malnutrition because of the physical properties of the feces that are formed from it, rather than because of a lack of any antiscorbutic substance.

The investigations of Cohen and Mendel[4] at Yale University are not in harmony with the belief that intestinal stasis is the sole predisposing factor in the production of scurvy or that the action of well known antiscorbutics can be explained as due to their laxative effects. For example, in the case of certain selected diets a small amount of milk ingested daily permitted the onset of symptoms of scurvy, while larger quantities, which were not less constipating, caused the scorbutic symptoms to disappear. Moreover, aids to the ready elimination of feces, like differing amounts and kinds of roughage, caused no corresponding change in the course of the disease. The Yale investigators conclude that roughage in the diet plays, if anything, a minor accessory rôle in the prevention of scurvy. This disease is not essentially dependent on constipation as a causative factor, though the latter may aggravate the symptoms.

Hess has expressed himself in a similar vein:

> Observations of many cases of infantile scurvy have convinced us that constipation plays no essential rôle in this disease. In reviewing the many cases that we have seen we find that the infants were not constipated to a greater degree than normal babies, and that the disorder bore no parallel relationship to the activity of the bowels. Furthermore, as brought out in a recent paper, potato, which is a sovereign remedy for scurvy, is not a laxative, and malt soup preparations, which most readily lead to this disorder, are rather laxative than constipating. To this evidence may be added a recent experience that infantile scurvy does not yield to treatment by liquid petrolatum, but that its symptoms are rapidly alleviated by small additions of orange juice to the dietary, so small as to be without apparent effect on the bowels.

The accord between the English investigators, Chick, Hume and Skelton,[5] and the American workers just quoted serves to keep scurvy for the present in the domain of diseases due to deficiencies of nutrition, and gives renewed significance to the careful study of antiscorbutic agents. For, as Hess[3] has remarked, if the protective or curative values of antiscorbutic foods are, as McCollum and Pitz have recently contended, merely dependent on their laxative properties, and interchangeable with laxatives, such as liquid petrolatum or phenolphthalein, then scurvy is in no sense whatsoever due to food deficiency.

THE RELATION OF SANITATION AND DRAINAGE TO MALARIA

In the scheme of disease prevention, sanitation is an essential factor; and in no disease has this been more decisively established than in malaria. Malaria flourishes chiefly in tropical or semitropical climates where drainage is defective, and consequently where conditions are propitious for the breeding of mosquitoes. The campaigns in eastern Europe have afforded excellent opportunities for emphasizing the force of this statement. In the Struma and Vardar valleys, consisting of marshy lands in which mosquitoes abound, malaria was extremely prevalent. Entente armies have been stationed there for years. The reclamation and drainage undertakings set in motion by British and French engineers have had the result already of destroying many of the mosquito breeding haunts and have decreased the prevalence of malaria. When the drainage plans have been completely carried out, these regions, which have been practically uninhabited for generations, will again become fruitful tracts of land able to support a large population.

Another conspicuous instance of the good effects of drainage and sanitation is provided by the island of Cyprus.[1] In 1878 malaria was so prevalent in this island that it was referred to as a "hotbed of malaria," and troops were withdrawn from the island. Antimalarial measures were inaugurated there in 1913 by Sir Ronald Ross. These measures included drainage, the clearance of land by cutting grass, and the stocking of tanks with goldfish. During this war both troops and prisoners have been quartered there, and yet no primary cases of malarial infection have occurred among the prisoners, while the incidence rate of malaria among the troops has been 0.4 per cent. Assistant Surgeon-General H. R. Carter has pointed out[2] that mosquitoes will breed freely in wild celery, which grows in water varying from 2½ to 6 feet in depth, and in lotus beds where the leaves of the plant have fallen into the water and adhered together as they decay. The water hyacinth, *Eichhornia crassipes,* although a highly ornamental plant, provides one of the most frequent means of shelter for the mosquito. In the Madras Presidency an outbreak of malaria was due to the fact that the plant afforded a convenient refuge to mosquitoes.

A problem of a similar nature confronted Colonel Truby, M. C., U. S. Army, who, in his annual report as chief medical officer of the health department of the Panama Canal, stated that the water lettuce, *Pistia stratiotes,* gives shelter to *Mansonia titillans,* and that additional studies will be carried on from time to time with the view of discovering an economical and practical method of eradicating the plant and its associated mosquito. If malaria were extirpated, as it is possible for it to be extirpated, the tropics would lose a great deal of their unhealthfulness for white people.

Sanitation, agriculture and economics are inextricably bound together, and the war, in the instances of Mesopotamia and Greece, has once again brought into prominence the fact that drainage and other obvious sanitary measures will abolish the mosquito and render the tropical and subtropical zones sufficiently healthful for the white man. Thus we may reasonably hope that the time is not far distant when the wonderfully fruitful soil of tropical climates may be cultivated and made useful in the support of humankind.

---

THE UTILIZATION OF CALCIUM AND SOME OTHER ELEMENTS IN CERTAIN VEGETABLES

"It is not difficult," the Food Guide of the United States Food Administration tells us, "to understand why vegetables and fruits are so important. Only a few are especially valuable as fuel or as a source of protein, but almost all are high in mineral salts and can supply the 'roughage' desirable in the diet. Some also contain the vitamins, the leafy vegetables being especially valuable because, like milk, they contain the two kinds. The 'green,' leafy vegetables, like spinach, cabbage, Brussels sprouts, asparagus and lettuce, are the ones that help most in these last ways—'protective foods,' they have been called. They are rich in the iron, calcium and other minerals that some of the other foods lack. The use of plenty of these vegetables should go far toward keeping up health."[1]

Hasty generalizations of this sort, helpful as they may be, are liable to include much that is conjecture or derived from reasoning by analogy. It is the duty of the contemporary science of nutrition to check up every pronouncement of fundamental scope so far as it is not already firmly established on the bed rock of experimental observation. On one aspect of the use of certain vegetables in the dietary, recent investigations have shed some light. In infant nutrition, suitable plant products, such as carrots and spinach, have come more and more into dietary vogue within the past two decades. It is understood that they are comparatively rich in calcium, an element essential to the nutrition of growth, found at best in small quantities in cereals and flesh products, but abundant in milk. The value of these green vegetables has been attributed in part to their effect on the mineral metabolism.[2] McClugage and Mendel[3] of the Yale Laboratory of Physiological Chemistry have specially investigated the relative availability of the calcium of carrots and spinach in the animal economy. Their results show that when these vegetables were added to the diets of animals the calcium was not so well utilized as is the calcium in milk or in calcium carbonate. Hence McClugage and Mendel arrive at the deduction that so far as calcium is concerned, if milk were not available, the addition of a suitable calcium salt would be quite as rational a procedure as a vegetable addition. Furthermore, in order to add to the diet an appreciable amount of calcium from a vegetable source, it would be necessary to feed large quantities of the vegetables, which in itself is a rather difficult procedure in the case of infants.

[3] McClugage, H. B., and Mendel, L. B.: Experiments on the Utilization of Nitrogen, Calcium and Magnesium in Diets Containing Carrots and Spinach, Jour. Biol. Chem., 1918, **35**, 345.

As the Yale investigators remind us, this outcome does not speak in any way against the vegetables as sources of vitamins, iron or other dietary factors. The implied warning is that it may be an unsafe procedure to use vegetables extensively as a dietary substitute for milk in the nutrition of children unless they respond to these foods differently from the laboratory animals on which experiments were made. It is always wise to be prepared to meet the contentions of the faddist, who is likely to see only advantages and be blind to the shortcomings of his preferred practices.

Current Comment

THE HEALTH OF THE NAVY

The annual report of the Surgeon-General of the Navy, covering the fiscal year 1918, has just been received. Under present circumstances it is a more interesting and human document than in normal times of peace. The rapid expansion in the personnel of the Navy during the war included enlargement of the Medical Corps to over 3,000 officers, this enlargement following the widening of the Navy's entire sphere of activity. The activities, as pointed out by Surgeon-General Braisted, included the establishment of hospitals abroad, care of the battleship fleet, medical personnel for the marines and the manning of three hospital ships, and finally, the care of the great inland training station, as well as of several training stations situated on the coasts. The health of the Navy has been excellent, affected only by epidemics which have seized the community in general. The general admission rate for the entire Navy for all causes—disease, injuries and casualties—during the six months from Jan. 1 to June 30, 1918, is 716.50 per thousand per year as compared with the average annual rate of 624.23 for the eight peace years from 1909 to 1916. The annual death rate for disease for the six month period was 5.9 per thousand as compared with 2.7 for the ten year period from 1907 to 1916. It is pointed out that this record is related to the severe weather conditions of last winter so that the death rate for disease during the first three months was 8.9 and for the second three months, 3.3—a figure approaching the average for peace times. The work of all the different departments of the Naval Medical Corps is described in detail, as well as the sanitation of individual ships and stations. Special reports are devoted to the various diseases that have been prevalent, as cerebrospinal meningitis, the pneumonias and measles. In discussing the venereal diseases, it is pointed out that the figures now obtainable from men examined for induction into the Army under the selective draft indicate that the percentage of men in either the Army or the Navy infected with venereal disease is lower year after year than the percentage of males of corresponding ages in civil life. The records for 1918, while higher than for 1917, are nevertheless much lower than for the previous eight or nine years. This report is of especial interest to those studying sanitation problems of military forces.

WHY NOT ISOLATION AND QUARANTINE?

The present epidemic of so-called influenza is as contagious, and certainly as fatal, as smallpox, scarlet fever or measles. While we know little of its etiology or mode of transmission, we know as much of these two factors in this disease as we know of the same factors in the three other diseases mentioned. There is reason to believe that all four spread by contact—from man to man. When smallpox, scarlet fever or measles is prevalent, rigid isolation and quarantine are enforced, and it is quite certain with at least a fair measure of success. Should not the same methods of prevention be more vigorously adopted in the present epidemic? When it is realized that already from one fourth to one third of the population of this country has been subject to the disease, that more than 300,000 persons have died as a result of the infection, the suggestion that every case of influenza be isolated and that quarantine against these cases be rigidly enforced is worthy of serious consideration.

A BACTERIAL FACTOR IN AUTOINTOXICATION

Before the complex of uncertainties vaguely described as gastro-intestinal autointoxication can be intelligently unraveled and understood, it will be necessary to know far more than is at present appreciated regarding the manifold factors involved. Although some would limit the use of the term "autointoxication" to poisoning with products of cellular metabolism, it is practically impossible at present to separate this eventuality from the effects that may be traceable to the absorption of toxic products formed by putrefaction within the alimentary canal or introduced into it with the ingested food. Judging by the fact that transformation products of phenol are almost always present in the urine, we may properly assume that this aromatic compound is a common product of the bacterial disintegration of proteins in the gastro-intestinal tract, even if it be admitted that a small amount may be of endogenous origin.[1] In cases of ileocecal fistula in which the food residues do not delay in the large intestine, phenol derivatives are usually absent from the urine. Furthermore, in the few reported classic instances of animals kept alive without bacteria, the same failure of phenol production has been reported.[2] The immediate precursors of phenol are assumed to be the aromatic amino-acids tyrosin and, perhaps, phenylalanin, both of which are obtained as familiar digestion products of proteins. The question as to the micro-organisms specifically responsible for the reactions involved has remained more uncertain. Indol formation, another phenomenon long defined as a characteristic feature of autointoxication and for which the tryptophan group in the protein molecule is essential, has been attributed to the *Bacillus coli* group so abundantly found in feces. Recent studies by Rhein[3] at the Hygienic Institute in Posen have led him to conclude that the familiar production of phenol in the human alimentary canal is due to a special race or type of *B. coli* designated as *B. coli-phenologenes*. It is characterized by failure to form indol. If this conclusion is further substantiated, the observation will serve to add another fact of definite character with the help of which the complete story of autointoxication can perhaps ultimately be written.

THE PSYCHOLOGY OF THE HEALTH OFFICER

An unbiased observer after listening to the discussions concerning influenza at the session of the American Public Health Association would come to the conclusion that some of those present were concerned largely with justifying their course of action during the epidemic; in other words, that they had not come with an open mind. Argument after argument was made on the basis of broad generalization or of unverifiable statistics. This is especially to be regretted because most of the points under discussion concerned questions susceptible of scientific proof. None of the health officers need to apologize for what they have done or left undone. The prophylaxis and treatment of this disease on a scientific basis depend on an accurate knowledge of its etiology and epidemiology. But the etiology of the epidemic is unknown, and its mode of transmission is unknown. Health officers had no guide of action and, by the very nature of things, could not have such a guide as long as our knowledge of the disease is as meager as it is. All had done what they thought was for the best; this was indicated by the spirit of the meetings and the discussions. These showed that the health officers of the states and of the large and small communities realized their responsibility and were more than anxious to do the right thing.

Stammering.—Treatment rests on the principle of educated self-control. Concrete application of this principle is directed, first, toward conscious control of the peripheral speech mechanism, and, second, toward direct control of the emotional and nervous disturbance.—E. L. Kenyon.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending December 13, there were in the Medical Corps 31,045 officers, a decrease of fifty-nine since the previous week. This personnel includes four major-generals, five brigadier-generals, 219 colonels, 513 lieutenant-colonels, 2,487 majors, 10,098 captains and 17,719 lieutenants. There were in active service 30,222, a decrease of 157 since the previous week. Discharges to date include 4,148 officers.

Medical Division of the Provost-Marshal's Office Disbanded

The Medical Division of the Provost-Marshal's Office is being disbanded. Lieut.-Col. Hubert Work and Capt. D. Chester Brown have received honorable discharges and have returned to their homes. Col. F. R. Keefer will shortly return to service with the regular Medical Corps.

Colonel G. L. Edie Recommended for Promotion

Colonel Guy L. Edie of the Army Medical Corps, at present chief surgeon at Base Section No. 5, services of supply, France, has, it is reported, been recommended for promotion to the rank of brigadier-general by Gen. George H. Harries, commanding general of the base. In making this recommendation General Harries says:

> It would be impossible to fairly set forth, within the limits of such a communication as this, the many reasons why Colonel Edie is deserving of recognition. In a situation where difficulties mounted so high and advanced so swiftly that they seemed at times to be almost overwhelming he accomplished greatly. Despite the lack of medical personnel and the construction which he strove to secure, he never approached failure. Especially was he supremely successful during the epidemic of influenza-pneumonia, which came to us on transports; for the service he then rendered the Army owes him more than it can ever pay. An officer of rich experience, mature judgment and keen initiative, he has earned much more than I now recommend be given to him.

Extracts from Weekly Bulletin A. E. F., No. 32

Nov. 18, 1918

This bulletin calls attention to the necessity for continued warfare against disease in the A. E. F., and points out that the job is 99 per cent. prevention of disease. Special attention again is called to the necessity of plenty of fresh air in disease prophylaxis. The weekly report of disease indicates that diphtheria again shows an excessive rate, the cases being reported widely from the A. E. F., especially concentration of cases occurring at hospital centers. It is said that many of the cases are secondary cases developing within the hospital and among the hospital personnel. Good aseptic ward technic and the conscientious wearing of masks it is believed will prevent much of the secondary infections.

A warning is issued to troops not to open boxes which the enemy has left behind in certain regions. These wooden boxes bear the inscription "Vorsicht! Infectiöse Materiel."

An Item for the Sports Department

In the final battle of the season the Camp Greenleaf football eleven defeated the eleven from Camp Dix by a score of 34 to 0. The Camp Greenleaf team was entirely medical, trained by doctors and composed of the enlisted men of the medical department. According to Washington papers, the Camp Greenleaf eleven thus become the Army football champions of 1918.

Decorated for Bravery

Decorations for bravery in action have been conferred on the following medical officers of the American Expeditionary Forces: Capt. Earl V. Morrow, M. C., U. S. Army, Portland, Ore.; Capt. George P. O'Malley, M. C., U. S. Army, Cleveland, on duty with a British unit, the distinguished service medal by the British government for bravery in rescuing wounded under fire; Lieut. Frank H. McGregor, M. C., U. S. Army, Mangum, Okla., awarded a medal for bravery by the British forces; Ernest C. Rowland, Allentown, Pa., an American Army ambulance driver serving with the French army, although wounded by shell fragments, stuck to his post and delivered the wounded under his care to the hospital, has been awarded the Medaille Millitaire and Croix de Guerre with palms.

Prisoners

It is reported that Lieut. Henry L. Rothman, M. C., U. S. Army, Washington, Mo., is a prisoner in Germany.——It is reported that Capt. Benjamin P. Burpee, M. C., U. S. Army, Manchester, N. H., is a prisoner in Camp Villingen, Germany, and is in good health.

Medical Officers Gassed

It is reported that the following medical officers on duty with the American Expeditionary Forces in France are suffering from having been gassed: Lieut. Robert H. Breslin, M. C., U. S. Army, Providence, R. I., on duty with the 103d Infantry; Lieut. Eugene H. McCaffery, M. C., U. S. Army, Sprague, Wash.; Capt. Fred A. Lieuallen, M. C., U. S. Army, Portland, Ore.; Major Philip G. Cole, M. C., U. S. Army, Helena, Mont.; James P. H. Ruddy, Scranton, Pa., and Lieut. Walter T. Bronson, Pueblo, Colo.

Wounded

The following medical officers are reported to have been wounded: Lieut. Bernard Bolka, M. C., U. S. Army, Chicago, slightly; Lieut. Sloan A. Brown, M. C., U. S. Army, Coraopolis, Pa., slightly; Lieut. Thomas S. Williams, M. C., U. S. Army, Dallas, Texas, severely; Major Frank E. Winter, M. C., U. S. Army, Santa Ana, Calif., severely; Lieut. Herbert G. Hempler, M. C., U. S. Army, Creal Springs, Ill., degree undetermined; Lieut. Samuel J. Benoit, M. C., U. S. Army, Gardner, Mass., degree undetermined; Lieut. Charles C. Ryan, M. C., U. S. Army, Republic, Pa., severely; Lieut. Robert LeRoy Leighton, M. C., U. S. Army, Spring Lake, N. J., slightly; Lieut. J. Armin Stackhouse, M. C., U. S. Army, Ambler, Pa., degree undetermined; Lieut. Lomax Gwathmey, M. C., U. S. Army, Norfolk, Va., degree undetermined; Capt. William S. Horn, M. C., U. S. Army, Fort Worth, Texas, severely; Lieut. Milford Arthur Leach, M. C., U. S. Army, Grand Rapids, Mich., slightly; Lieut. Edward S. Huckins, M. C., U. S. Army, Bay City, Mich., degree undetermined; Lieut. Lloyd E. Wurster, M. C., U. S. Army, Philadelphia, severely.

To Garden City, N. Y., from Mineola, Lieut. E. R. VAN COTT, Diamondville.

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Passed Asst. Surg. F. A. CARMELIA, proceed to Columbus, Ohio, and Wheeling and Charleston, W. Va., for conference concerning the influenza situation.

Asst. Surg. R. P. SANDIDGE, proceed to necessary places in the state of Virginia for duty in connection with extracantonment sanitation.

Asst. Surg. R. W. HART, proceed to Stapleton, N. Y., for duty at the Marine Hospital.

Acting Asst. Surg. R. E. GRAMLING, proceed to necessary places in Kansas, including Topeka and Kansas City, for conference relative to venereal disease control.

Acting Asst. Surg. PARK HOWELL, proceed to Pensacola, Florida Quarantine Station for temporary duty.

Acting Asst. Surg. J. I. WHITTENBERG, proceed to Lexington and other places in the state of Kentucky for duty in the influenza control.

Constructing Engineer N. V. PERRY, proceed to Dawson Springs, Ky., to inspect certain property tendered for hospital uses.

Sanitary Engineer L. C. FRANK, proceed to Jackson, Miss., to attend conference of state health officers.

Sanitary Engineer H. W. STREETER, proceed to Baltimore, Md., for duty in epidemiological studies in influenza.

Scien. Asst. G. H. DECELL, proceed to Baltimore, Md., to collect data relative to the epidemiology of influenza.

Scien. Asst. W. L. WOOD, relieved at Alexandria, Va., proceed to Philadelphia, Pa., for duty in shipyard sanitation at Chester, Pa.

Chemist OLIVER H. SCHUNK, proceed to Milwaukee, Wis., to investigate pollution by industrial waste of the city water supply.

Chief Sanitary Inspector A. C. SHAW, proceed to Columbus, Ga., to study the milk and dairy situation in extracantonment zones.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST; SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

New County Officers.—The Maricopa County Medical Society at its annual meeting in Phoenix elected the following officers: president, Dr. Robert R. Brownfield; vice president, Dr. Harlan P. Mills; secretary, Dr. Kimball Bannister, and treasurer, Dr. Henry T. Bailey, all of Phoenix.

COLORADO

Medical Veterans of the World's War.—Officers and members of the Medical Corps of the United States Army, and of the Federal Draft and Advisory Boards met at the capitol, Denver, at the call of Capt. Horace G. Wetherill, M. C., U. S. Army, medical aide to the governor, to take preliminary steps toward the organization of the Colorado unit of the Medical Veterans of the World's War. Members of nineteen medical advisory boards, of seventy local boards of the several counties and of two district boards, in all about 600, are eligible to membership. Captain Wetherill presided and was instructed to appoint a committee on permanent organization.

ILLINOIS

Palmer to Move Office.—Dr. George T. Palmer, assistant director of the state department of public health and president of the Illinois State Tuberculosis Association, expects to move his office from Chicago to Springfield, by January 1.

Fire at Camp Grant.—Fire of unknown origin at Camp Grant, Rockford, is said to have destroyed the building occupied by the medical examination board handling discharge examination work, and it is said that 6,000 qualification cards and records of examination were lost.

District Society Meeting.—At the annual meeting of the North Central Illinois Medical Association held in Dixon, December 10, Dr. Otho B. Will, Peoria, was elected president, Dr. John C. White, Seatonville, vice president, and Dr. George A. Dicus, Streator, was reelected secretary-treasurer.

Chicago

Fire at State Hospital.—A fire at the Dunning State Hospital, December 11, did great damage to the tuberculosis building, a one-story frame structure, from which 400 patients were removed, many of them ill with influenza. No casualties occurred.

Special Number.—In celebration of the meeting of the American Public Health Association in Chicago during the week of December 9, the city department of health issued a special number of the *Bulletin of the Chicago School of Sanitary Instruction.* This bulletin gives details of the organization of the health department, together with a description and statistics of the activities of the various divisions and bureaus, including special investigations conducted by the department in 1917 and 1918.

Dudley Leaves Active Faculty.—Dr. Emilius C. Dudley, after thirty-seven years as professor of gynecology at Chicago Medical College and Northwestern University, Medical School, has retired from the faculty and has been made emeritus professor of gynecology. In commemoration of his long and faithful work for the school, the faculty gave a dinner in his honor, December 12, at which Dr. Archibald Church, Chicago, presided and at which addresses laudatory of Dr. Dudley were made by President Holgate of the Northwestern University, Dr. E. Quine, Dean Arthur I. Kendall, Major Samuel C. Stanton and Lieut.-Col. Nathan William McChesney.

KENTUCKY

State Aid to Visiting Nurses.—The state has a law enacted in 1918 providing that from any funds in the treasury not otherwise appropriated the state board of health may appropriate to any county, tuberculosis district commission, or other public welfare organization, a sum not to exceed $25 a month to pay the state's part of the salary of a visiting nurse employed under the act. Such nurses have been made a part of the health system of the state under a rule of the state board made on the advice of the attorney-general for the purpose of making legal the payments named.

Every Physician a State Health Officer.—Recognizing that the weak point in public health organization is the failure to secure and act promptly on reports of contagious or infectious diseases, the state board of health has endeavored to remedy this situation by making every physician in the state holding a certificate to practice medicine or other system of healing a permanent sanitary inspector of the board. A certificate is issued to such persons giving authority and instructions to isolate all cases of influenza or other communicable diseases for a period of ten days after recovery, and all cases suspected as such until it is known that it is not a communicable disease. They are required to report all cases of such disease to the county or city health officer within twenty-four hours. Delay in reporting or in taking proper action in regard to such infectious cases has been a handicap in all epidemic work, and has proved especially disastrous in the prevailing epidemic of influenza.

LOUISIANA

Mrs. Matas Dies.—Mrs. Adrienne Matas, partner in all professional labors and activities of Dr. Rudolph Matas, New Orleans, died December 10, from pneumonia following influenza. She regularly accompanied her husband to the meetings of the American Medical Association. For several years she had been an invalid, suffering with nephritis, and for the last five months, angina pectoris.

Vital Statistics of the State.—Louisiana has at last been placed in the registration area of the United States by the census bureau, so far as statistics of deaths are concerned. To obtain this recognition it is necessary that at least 90 per cent. of all deaths shall be reported. Louisiana is the fifth Southern state to be admitted, and the first in the Southwest to qualify.

Health Board Activities.—Dr. Oscar Dowling, Shreveport, president of the state board of health, has issued a formal statement setting forth the importance of the "Come Clean" campaign in which he is now engaged for the abolishment of diseases arising from social vice. The campaign is now an antivice crusade by a crusade against venereal disease. It is being conducted by the state board of health under orders of the United State Public Health Service, and its details are first, to clean up and enforce all repressive measures, second, to establish medical work in clinics and detention homes, third, to instruct the public through pamphlets, exhibits and literature, and fourth, to provide wholesome recreation, attractive lounging places, organized sports, reading rooms, and other good amusements.——Dr. Oscar Dowling has just returned from a two weeks' trip through the state undertaken in an effort to establish at various points a series of laboratories where physicians may be assisted in making quick and active diagnosis. The tentative points for laboratories are Shreveport, Monroe and Baton Rouge, and one will probably be established in the southwestern part of the state.

MARYLAND

New Officers.—At the meeting of the Baltimore City Medical Society, December 6, the following officers were elected: president, Dr. Guy L. Hunner; vice president, Dr. Harvey G. Beck; secretary, Dr. Emil Novak, and treasurer, Dr. William S. Gardner, all of Baltimore.

Personal.—Lieut. Alexander J. Gillis, Baltimore, has been awarded the British Military Cross. Lieutenant Gillis is confined to a hospital at Wandsworth, London, recovering from shell wounds in his side, received while on duty with the British Expeditionary Forces.

Fresh Outbreak of Influenza.—The increase in the number of new cases of influenza being reported to the health department has led the Advertising Club to request Health Commissioner John D. Blake to take immediate steps to prevent another epidemic. The health department is prepared to act should it become necessary to do so, but at the present time Health Commissioner Blake sees no reason for drastic action. Dr. Blake blames what appears to be a fresh outbreak of Spanish influenza on the failure of people to exercise care in keeping away from crowds after he lifted the bans that were put into effect during the late epidemic.

Jewish Health Board Organized.—At a meeting of the Jewish Health Board, recently organized, the following officers were elected: A. Ray Katz, president; Dr. Harry J. Moss, vice president; Herbert Wyle, treasurer, and Mrs. Isidore, secretary. The board will undertake to solve the questions of health and sanitation in Jewish families whenever possible. The organizations interested are: Hebrew Hospital, Social Service Department Hebrew Hospital, Hebrew Benevolent Society, Jewish Country Home, Jewish Home for Incurables, Young Ladies' Benevolent Society, Council Milk and Ice Fund, and the Jewish Home for Consumptives.

MINNESOTA

Death of Mrs. Hilbert W. Hill.—The death is announced of Mrs. Hill, wife of Dr. Hilbert W. Hill, St. Paul, the executive secretary of the Minnesota Public Health Association. The death occurred at the University Hospital, Minneapolis, November 27, from pneumonia following influenza. Mrs. Hill was active in child welfare work.

Course in Public Health Nursing.—The *Minnesota Public Health Association Journal*, December 5, announces that the four months' course in public health nursing, arranged for by the University of Minnesota in cooperation with the Minnesota Public Health Association, is now in operation. The course has been provided as an emergency measure to remedy the shortage of nurses and is offered to a limited number of graduate or senior nurses from accredited training schools. It is expected that a similar course extending over a period of at least eight months will be offered at the University hospital during the coming year.

NEW YORK

Bay Ridge Wants Hospital Returned.—At a recent meeting of the Medical Society of Bay Ridge, resolutions were adopted requesting the United States to rescind its action in taking over the Norwegian Hospital, inasmuch as taking over the hospital has deprived a district six miles square, with an approximate population of 300,000, of proper hospital facilities.

Typhoid at Herkimer.—The typhoid fever epidemic in the village of Herkimer is now believed to be well under control. During November only twenty-five cases developed against 105 cases during October. The majority of the new cases are believed to have been developed by contact rather than by water pollution. The original source of the epidemic was impure water.

Staff of Bureau of Venereal Diseases.—The following permanent appointments have been made to the staff of the Bureau of Venereal Diseases of the state department of health: Dr. Joseph S. Lawrence, Albany, chief; Dr. Edward H. Marsh, Brooklyn, consultant; Dr. Walter S. Goodale, Buffalo, hospital and dispensary inspector and organizer; Dr. Frederick S. Honsinger, Syracuse, lecturer on social diseases; Maud Casey, supervising nurse and social worker.

State Conference of Charities.—The State Conference of Charities and Corrections was held in Rochester, December 10 to 12. At the session of December 11, the problems of mental hygiene were discussed by Dr. Charles W. Pilgrim, Poughkeepsie, president of the State Hospital Commission, and Dr. Walter B. James, New York City, chairman of the state commission of the feebleminded, spoke on "The Duty of the Medical Profession and the State Toward the Mentally Defective."

Influenza Epidemic and Infant Mortality Rate.—The New York State Health Department calls attention to the fact that many babies were born during the period of the influenza epidemic, unattended by either a physician or a midwife. Since the infant mortality rate is based on the number of reported living births, it is very important to have all such unattended births reported by physicians, midwives and nurses as soon as they are discovered in order to prevent the recording of a high infant mortality rate that is not in accord with actual conditions.

Personal.—Dr. Cassar Smith, Olean, is reported seriously ill as the result of a cerebral hemorrhage.——Capt. H. Judson Lipes, M. C., U. S. Army, Albany, formerly of the Sanitary Corps of the One Hundred and Fifth Regiment, at Troy, who was seriously wounded in France, underwent an operation in New York, December 4.——Dr. Esther E. Parker, Ithaca, has returned after thirteen months spent in clinical and roentgen-ray work in France.——Dr. Ralph E. Clogher, Utica, has been invalided home after serving with the medical department of the American Red Cross in France.

Influenza Commission.—The first work of the Influenza Commission appointed by Governor Whitman, October 21, of which Dr. Hermann M. Biggs is chairman, is now under way. The attempt is being made to reach a definite conclusion as to the value of influenza vaccines in preventing the disease. A large number of different groups of people in institutions, cantonments, factories, hospitals, prisons, and patients of various physicians will be studied. Surveys of certain cities where influenza has been most severe will be made, not only in this state but in others, in order to study the cause of the local epidemic, the probable point of entry, the method of spread, types of the disease, the effect of age, sex, and nationality, and the incidence, mortality and morbidity rates. It is probable that in the states that have not been invaded, especially in the west, special studies will be made in regard to prevention by vaccines and the value of quarantine.

New York City

Personal.—Dr. William V. P. Garretson has been appointed consulting neurologist to the Hospital for Functional Reeducation of Disabled Soldiers and Sailors affiliated with Cornell University Medical College.——Major Sigmund Politzer, M. C., U. S. Army, attached to Base Hospital No. 1, was thrown from his car in a collision between automobiles, November 30, suffering a fracture of the skull.——Dr. Pang Yuen Tseo, a Chinese woman, has been assigned to the ambulance staff of Bellevue Hospital.

Influenza and Pneumonia.—The new cases of influenza and pneumonia reported to the health department show that the extent of the disease has neither increased nor diminished during the past few weeks, the number of cases reported daily varying from 100 to 200. The department of health points out that the number of cases will probably continue higher than the average and that sporadic outbreaks are to be expected. A comparison of the mortality rate for influenza in New York with that of other eastern cities shows that New York had a death rate of 27 per thousand population, against 54 in Philadelphia, 47 in Baltimore, 41 in Boston, 34 in Buffalo and 32 per thousand in Newark.

PENNSYLVANIA

Academy Meeting.—At the annual meeting of the Harrisburg Academy of Medicine, held December 6, Dr. M. Howard Fussell, professor of medicine in the University of Pennsylvania, delivered an address on influenza.

Tablet to Influenza Victim.—A bronze memorial tablet in memory of Dr. William B. Shick in Logan was unveiled in the Logan Methodist Episcopal Church, December 8. Dr. Shick died a martyr of his profession during the recent influenza epidemic.

University Offers Occupational Courses.—The school of occupational therapy for maimed soldiers, now stationed at the University of Pennsylvania, is to be united with the university proper and the work of men covers industrial and scientific subjects, including lectures on physiology education and correction for mental speech defects.

Personal.—Lieut.-Col. Richard H. Harte, head of Base Hospital Unit No. 10, one of the first American Hospital units to arrive in France, is in the Pennsylvania Hospital recovering from a serious operation.——Dr. Edward Martin, major in the Medical Reserve Corps and stationed at a camp in Georgia, has ben elected emeritus professor of surgical physiology at the University of Pennsylvania.——Dr. Herman D. Boyles, Newcastle, has been appointed coroner of Lawrence County to fill the unexpired term of the late Dr. Elmer P. Norris.

WEST VIRGINIA

Personal.—Dr. Vincent T. Churchman, Charleston, has succeeded Dr. Floyd F. Farnsworth, Frenchton, as president of the state health council, the latter having been appointed director of the Bureau of Venereal Diseases with headquarters at Charleston under the supervision of the United States Public Health Service.

WISCONSIN

Personal.—Dr. Henry C. Sibree has resigned as health officer of Sturgeon Bay, and has been succeeded by Dr. Thomas C. Proctor. Owing to illness of Dr. Proctor, Dr. Joseph J. Curtin has been placed temporarily in charge of the health office.

Sanatorium Item.—The new tuberculosis sanatorium for LaCrosse County, the tenth institution of its kind to be erected in the state, has been completed at a cost of $95,350.98. The institution has accommodation for forty patients, and already has thirty-five patients and a waiting list more than sufficient to tax the accommodation of the building. Miss L. S. Dietrichson is superintendent of the sanatorium.

CANADA

Unification of Health Boards.—The Essex Border Utilities Commission at the meeting held in Windsor, December 2, expressed themselves favorably toward the unification of the health boards of the five border municipalities of Ford, Walkerville, Windsor, Sandwich, and Ojibway, and decided to ask Dr. John W. S. McCullough, chief medical officer of health of Toronto, for suggestions looking toward a joint system of health inspection.

Hospital News.—A hospital building to cost $500,000 is to be erected near Woodbridge, Ont., about 15 miles from Toronto, by the Soldiers' Civil Re-Establishment. The cost is to be borne jointly by the provincial and federal governments. The site consists of 175 acres. It is to be used for patients with tuberculosis——The Royal Air Force Buildings at Beamsville, Ont., near Hamilton, have been inspected by Dr. Edward Ryan, Kingston, Ont., assistant director of invalided services, Toronto military district. It is quite likely they will be used for returned soldiers.

Personal.—William Edward Gallie, M.B., of the University of Toronto has received a diploma from the Royal College of Surgeons, England.——Among those who have recently returned from overseas are: Major A. D. Irvine, Montreal; Major G. M. Foster, Lieut.-Col. Alfred T. Bazin, Montreal, and Lieut.-Col. Gilbert Royce, Toronto.——Major Wesley Wright Pirt, Carman; Capt. Frederick Charles A'Court; Capt. Henry Maclaren, Ottawa, Ont.; Capt. Henry Clinton Pearson, Toronto, and Capt. Wallace Balfour Seaton, Carman, Man., have been appointed to the board of pension commissioners.——Major Malcolm M. Crawford has been appointed registrar at the new Rosedale Military Hospital, Toronto.——Lieut.-Col. Thomas A. Starkey, professor of Hygiene in McGill University, has returned to Montreal from overseas. He has been appointed consultant in sanitation in the eastern military districts, 4, 5, 6 and 7.

Public Health Act of New Brunswick.—As provided in the Public Health Act, 1918, Province of New Brunswick, the province has been divided into three health districts, each under the supervision of a district medical health officer, who in turn is responsible to the minister of health, a member of the provincial government. The act in addition provides for a chief medical officer, a chief health officer and a chief of laboratories, who complete the central bureau of health. Under the act three branches of public welfare are administered by the same officers, namely, public health and sanitation, medical inspection of schools, and collection of vital statistics. One provision of the act provides that "special attention shall be given to child welfare." The bureau at present consists of Hon. William F. Roberts, M.D., minister of health, St. John, N. B.; George G. Melvin, M.D., D.P.H., St. John, N. B., chief medical officer; Harry L. Abramson, M.D., chief of laboratories, and three district medical health officers, Francis J. Desmond, M.D., Newcastle, N. B.; John F. L. Brown, M.D., Woodstock, N. B., and Joseph A. Wade, M D., St. Andrews, N. B.

GENERAL

Bayer Company Sold.—It it reported that the Bayer Chemical Company has been sold to the Sterling Products Company for $5,310,000.

Venereal Subjects' Travel Restricted.—Under an amendment to the interstate quarantine regulations announced by the Surgeon-General of the United States Public Health Service, persons having venereal disease must obtain a permit in writing from the local health officer before they will be permitted to engage in interstate travel. This permit must state that such travel is not dangerous to the public health.

Fenger Memorial Fund.—The directors of the Fenger Memorial Fund have set aside $500 for medical investigation. It is preferred to assist in work of a direct clinical bearing which may be carried out in an established institution, which will furnish the necessary facilities and ordinary supplies free of cost. Applications with full particulars should be sent to Ludvig Hektoen, 637 South Wood Street, Chicago, before Jan. 15, 1919.

Bequests and Donations.—The following bequests and donations have recently been announced:

Dr. D. Bryson Delavan, New York City, $25,000 and Woman's Hospital in the State of New York, New York City, two fifty-seconds of the estate of $40,000,000 by the will of Mrs. Russell Sage.

St. Lukes Hospital and the Society of Hospitals of New York City, each $17,436 by the will of Clara Sutton Macy.

Hamilton, Mont., Hospital, a donation of $1,000 by Mrs. Margaret Daley, Hamilton.

Enlargement of Marine Hospitals.—Assistant Surgeon-General Arthur M. Stimson, U. S. P. H. S., has asked the house building committee, with the approval of the secretary of the treasury, for an appropriation of $10,000,000 to provide the first 5,000 beds of the 13,000 estimated as necessary to care for discharged soldiers. The completed plan calls for hospitals costing $26,000,000, and in this is included a substantial addition to the United States Marine Hospital at Chicago.

Obligation to Provide Pure Water.—Damages totaling $50,462 on account of typhoid fever and other sickness alleged to have been caused by drinking polluted water on the lake steamer *South American*, sailing from Detroit, have, it is reported, been awarded to eleven plantiffs, passengers on the vessel. The damages were fixed by a master in chancery after Judge Tuttle of the United States District Court had held that the evidence submitted proved beyond question that typhoid fever was contracted on the trip. It was alleged that the steamer, after being out thirteen hours from Detroit, stranded in the Hay Lake Channel of the Sault Ste. Marie River, and that after using up the water in the tanks aboard, impure water from the river was supplied for drinking purposes.

Ten Million for Medical Research.—The will of Capt. James Raphael De Lamar bequeaths his residuary estate estimated at $10,000,000 to the Harvard University Medical School, the College of Physicians and Surgeons of Columbia University, and Johns Hopkins University, for medical research into the cause of disease and into the principles of correct living; for the study and teaching of dietetics and of the effects of different foods and diets on the human system. The will provides that, in connection with the foregoing purposes, fellowships, instructorships, scholarships and professorships be maintained, and clinics, dispensaries and other places for such study and research be provided. Provision is also made for the dissemination of the results of such study among the people of the United States. The will suggests that the legatees use any means they deem expedient for the purposes named, and requests that the fund be kept intact.

Social Hygiene Monthly.—This publication in the October number announces that the work begun and conducted for sixteen months under the auspices of the government, the Surgeon-General's Office, the Commissions on Training Camp Activities of the War and Navy Departments, through the Public Health Service, will not cease with the signing of peace, but that it is the desire to have it go on as a social movement. The monthly will continue publication on that basis and at present has a circulation of 30,000 copies. It is the intention to send the monthly without charge for an indefinite period to leaders of thought and action throughout the United States—to boards of health, educators, legislators, women's clubs, commercial bodies, labor leaders, clergy, etc. The work already accomplished, it is believed, could probably have been done under ordinary circumstances in a generation, and consequently the publication should not now be allowed to lapse.

Major-General Gorgas Investigating Yellow Fever.—In January, 1917, the International Health Board of the Rockefeller Foundation, with the permission of the Secretary of War, secured the services of Surgeon-General Gorgas to act as director of a commission to investigate yellow fever and malaria in Central and South America. In addition to General Gorgas, the commission consists of Henry R. Carter, clinician; Juan Guiteras, clinician and general adviser; Theodore C. Lyster, clinician; Eugene R. Whitmore, pathologist, and W. D. Wrightson, sanitary engineer. Preparations for carrying out this project had been practically consummated when the United States entered the world war making it impossible for General Gorgas to give up his official connection with the Army. Major-General Gorgas, having been retired on account of age, was again available for the work. Immediately on his retirement preparations were again entered into for carrying out the project as originally proposed, and last week he sailed for Ecuador as the first field of operations. Dr. N. E. Horner and other workers had preceded him. Accompanying him are Col. C. L. Furbush, who had acted as General Gorgas' executive officer during the latter's incumbency as Surgeon-General during the war, and Dr. Victor G. Heiser. The work is one in which General Gorgas has shown very especial interest; his sole ambition now, he says, is to rid the world of yellow fever.

Report of the U. S. Chemist.—The report of the Chief Chemist of the Department of Agriculture for the year reflects the influence of the war requirements in the way of personnel and direction of the work of the bureau, which necessitated the side-tracking or closing up of many lines in progress, and the rendering of all possible assistance to aid in winning the war. On account of the high price of drugs it is said that there was a tendency to revive flagrant types of adulteration, but with the aid of state and local authorities and the Food Administration it was often possible to suppress violations of the Food and Drugs Act more quickly than in normal times. The statistics of arrests and prosecutions with their results are given. Conservation of foodstuffs occupied some of the attention of the bureau, and the campaign for the extension of the use of new food fish was pushed, and such subjects as dehydration of vegetable products received considerable attention. Technologic investigations concerned such subjects as dust explosions, color investigations, naval stores, leather tanning and finishing materials, mildewproofing, fiber containers, the nutritive value of proteins and their chemistry, sugars and syrups, beverages and vinegar, fruits and vegetables, cereals and flour and the biologic causes of food spoilage and fermentation, beside researches in drugs and pharmacology, etc. In collaboration with other departments much good work was done, such as helping to secure fraud orders against fraudulent medicinal preparations, making recommendations to the railroad administration on the subject of standard refrigerator cars, assisting in food surveys, and methods of poisoning rats; this last in connection with the biological survey.

Influenza.—In a bulletin issued by the Public Health Service, December 11, a warning was given that the influenza epidemic is not passed and it is shown that severe epidemic conditions exist in various parts of the country. Since that date, according to later reports, the general condition has remained much the same, with improvement in some states and communities, and recurrences in others. The following summary by the service very well represents the present situation: In California increases in the number of cases of influenza are reported by San Francisco and several other cities in California. Indiana reports no improvement in the situation, except that the recent cases are milder. In Iowa a marked increase in the number of cases is reported. Kentucky reports a decided recrudescence in Louisville and some of the larger towns in the state. A few rural sections also report serious conditions. In contrast to the earlier part of the epidemic, the disease now appears to affect large numbers of schoolchildren. In Louisiana the disease has again increased in New Orleans, Shreveport, Lake Charles, Natchitoches, Standard, Zwolle, Noble, Convent and Kilbourne. At Lake Charles the recrudescence began December 1, and reached a height equal to that of the original epidemic. In Massachusetts the disease is apparently mild in character, but 5,500 cases were still reported last week. St. Louis reports more than 1,700 cases of influenza in three days, ending December 9. Mississippi reports a recrudescence in Hattiesburg. In Nebraska the situation is still very serious. New Jersey reports a substantial increase in a number of districts in which the disease had subsided and the disease is still prevalent throughout the state. From Ohio recrudescences are reported as occurring in Cincinnati, Cleveland, Columbus, Akron, Ashtabula, Bucyrus, East Liverpool, Salem, Lakewood, Medina, Franklin, Marion, Niles and Youngstown. The disease appears to be milder than during the first period of the epidemic. Pennsylvania reports a recurrence of influenza in a number of localities. Conditions are said to be worse than the original outbreak in Erie, Newcastle, and Johnstown. In South Carolina there is a general recurrence, especially in those sections where the epidemic raged some time ago. Vermont reports a recrudescence, but the disease appears to be milder in character. The state of Washington shows a sharp increase in the number of cases of influenza reported. West Virginia reports a recrudescence of the disease in Charleston, South Charleston, Bluefield and Clarksburg. In Wheeling conditions are said to be as bad as ever. The Surgeon-General advises the closing of the public schools on the first sign of the reappearance of the epidemic and points out that the disease apparently now tends to occur more frequently among schoolchildren.

FOREIGN

Roux to Retire.—Dr. Pierre Roux, for many years director of the Pasteur Institute, Paris, is about to retire and will be succeeded by Dr. A. C. Calmette, director of the Pasteur Institute of Lille.

Awards of the Royal Society Medals.—The *British Medical Journal* announces that the Copley medal this year goes to Prof. H. A. Lorentz, late professor of physics in the University of Leyden, for his researches in mathematical physics; the Davy medal to Prof. F. S. Kipping, professor of chemistry at University College, Nottingham, for his studies in the camphor group and among the organic derivatives of nitrogen and silicon; the Darwin medal to Dr. H. F. Osborn of New York, for his researches on vertebrate morphology and paleontology, and one of the Royal medals to Prof. F. G. Hopkins, professor of biochemistry in the University of Cambridge, for his researches in chemical physiology.

Deaths in the Profession Abroad.—Dr. **Ruperto Borras**, a member of the Uruguayan Medical Mission in France. After the return of the mission he remained in France, serving for many months at the Vaugirard military hospital at Paris.——Dr. **L. Merelli**, a prominent bacteriologist and serologist of Pisa, a victim of influenza.——Dr. **F. Todaro**, professor of anatomy at Rome, rector of the university and senator of the realm, aged 83.——Dr. **C. Remy**, professor of surgery at the University of Paris.——Dr. **Marty**, one of the oldest members of the Paris Académie de Médecine, a consulting chemist for the government.——Dr. **C. Colombo**, director of the Instituto kinesiterapico at Rome, and leader in the movement for physical culture for the young.——Dr. **O. Duurloo** of Copenhagen, president of the organized medical officers of the sickness insurance societies, aged 46.——Sir **H. Weber**, London, author of "Prolongation of Life," aged 95. He retired from practice at 80 but spent daily two or three hours in the open air, walking for 30 to 50 miles a week. He was among the first to advise the tuberculous to go to the mountains, even in winter. He was an honorary member of many learned societies, and with his son, Dr. F. Parkes Weber, published "Climatotherapy."

Fifth International Psychanalysis Congress.—The world war interfered with the meeting of this congress which had been planned to be held at Dresden. Besides the war, there were also certain difficulties in the way in connection with Jung's so-called "split" in the psychanalytic movement. A Netherlands physician, Dr. J. H. W. van Ophuijsen, now relates in the *Nederlandsch Tijdschrift*, Oct. 19, 1918, that the postponed congress was finally summoned to meet at Budapest, Sept. 28-29, and he describes his impressions of the congress as he made the trip from 's-Gravenhage, Holland, to Budapest. The main theme for discussion was the treatment of war neuroses, and the addresses by Ferenczi of Budapest, K. Abraham of Allenstein and E. Simmel of Posen, all concurred in estimating war neuroses as merely manifestations of the mechanism of the reaction to fright, the "fright neuroses" of peace times. The speakers were also unanimous in classifying these neuroses, with Freud, as anguish-hysteria and repression-hysteria. The number of cases of actual psychasthenia which have developed during the war was stated to be extremely small. Some brief communications discussed psychanalysis from the medical standpoint, and others discussed it in its application to other sciences. Between these two fields stood Freud's own address on "Ways for Psychanalytic Therapy." Jellinek and Roheim discussed "Friendship" and "The Ego Among Primitive Peoples," and Tausk outlined the principles for psychanalysis of the faculty of judgment. It was decided that the next international Psychanalysis Congress will be held in the Netherlands.

SOUTH AND CENTRAL AMERICA, MEXICO AND WEST INDIES

Resignation of Surgeon-General of Colombian Army.—The *Repertorio* of Bogotá states that Dr. M. Canales has resigned his position as chief of the medical department of the Colombian army.

Recent Deaths in the Profession.—Dr. E. Peña, director at one time of the Asistencia Publica of Buenos Aires, and initiator of the Hospital Tornu for the tuberculous.——Dr. V. Grau, city physician of Tres Arroyos, aged 71.——Dr. C. C. Sundblad, one of the founders of the Children's Hospital of Buenos Aires, aged 62.——Raphael Rubirosa, formerly a leading surgeon of the Dominican Republic, aged 33, died recently in the Manhattan State Hospital, New York.

Finlay Souvenir Volume.—The July-August number of the handsome journal issued by the national public health authorities of Cuba is entitled "Numero extraordinario en homenaje a la memoria de Dr. Carlos J. Finlay," on the anniversary of his death. It contains 197 pages, the size of the pages nearly as large as those of The Journal, and contains a photograph of Dr. Finlay and of the monument with his portrait bust which has been installed in the court of the headquarters of the public health department, the *Secretaria de Sanidad y Beneficencia.* All of Finlay's scientific works are reproduced or summarized, from 1865 to 1912. His communication on the transmission of yellow fever through an intermediary agent was presented to the International Sanitary Conference at Washington, D. C., in 1881. He did not specify the mosquito in that communication, but did this in his address before the Academia de Ciencias Medicas, Fisicas y Naturales, at Havana, Aug. 14, 1881. His address was republished in English and Spanish with the title "The Mosquito Hypothetically Considered as the Agent of Transmission of Yellow Fever." This journal issued by the National Public Health Service in Cuba, *Sanidad y Beneficiencia,* is always a large handsomely printed and illustrated journal with articles in Spanish and in English, bearing on matters of sanitation, vital statistics, etc. The director of the service is Dr. F. M. Capote, with Dr. Juan Guiteras and Dr. R. Menocal as subdirectors. The editor of the journal is Dr. E. Aragon. It is now in its twentieth volume.

MEXICO LETTER

Mexico City, Dec. 1, 1918.

Influenza

Influenza spread throughout the whole of the Republic, from north to south, during October and November. The central tableland was most seriously affected, the seacoast much less.

Puebla suffered most, the deaths totaling 300 a day, to a population of 100,000. The City of Mexico also had its daily death rate increase from seventy-five to 250. The disease appeared in a hemorrhagic form, a nervous with delirium and a gastro-intestinal form, but the highest mortality was in the respiratory form, frequently complicated with bronchopneumonia. It seems—in accord with what has been observed elsewhere—that young persons were affected most, and that persons who had the disease in a severe form in 1890 escaped it this time.

Bacteriologic research revealed nothing new, only the usual microbes of bronchitis and pneumonia being encountered, and the Pfeiffer bacillus only occasionally. Dr. F. Paz of the National Bacteriologic Institute, cultivated the *Micrococcus catarrhalis* from the blood of patients on two occasions.

At date of writing, the disease seems to have died out in this city and throughout most of the country.

Smallpox

There have been some cases of hemorrhagic smallpox at Puebla recently, but the disease has not spread owing to prompt isolation of the sick and vaccination of the others.

The Liberty Loan in Mexico

The Fourth Liberty Loan was a complete success in Mexico, as the quota assigned, $1,000,000, was oversubscribed, over $2,250,000 being collected. The bonds were bought not only by citizens of the United States residing here, but by citizens of the other Allied countries and by a goodly number of Mexican sympathizers with the noble cause. The boche propaganda tried to make the public believe that the business would be a failure, but like the propaganda itself, it lost influence and failed of effect because it had been placed in the hands of foreign adventurers or of Mexicans with antecedents not particularly honorable.

The Armistice

There was great rejoicing in the Capital when the news arrived that the armistice had been signed in Europe. The majority of the cultivated elements of the nation had sustained the cause of the Allies, and they joined with the foreigners in celebration of the victory. Impressive religious services were held as well as balls and banquets to celebrate the success obtained by the American arms in the cause of justice for the world. The most eloquent of Mexican orators, Lic. Urueta, said at one important meeting in Mexico that only imbeciles or the ignorant had sided with the cause which Germany sustained, and he was much applauded.

Personal

The director of the National Medical School, Dr. R. Amor, has been appointed *senador suplente* for the federal district.——Dr. A. F. Alonso, a well known ophthalmologist of San Luis Potosi, has recently moved to Mexico City. He represents the state of San Luis in the senate where he has always expressed opinions favorable to the cause of the Allied nations.——Dr. E. L. Abogado died recently. He was president of the local medical society, known as the "Pedro Escobedo." For many years he published a medical journal, now defunct, the *Cronica Medica Mexicana.*

New Society

A scientific and mutual aid society has recently been founded in Mexico, entitled the Sociedad Mexicana de Agricultura y Veterinaria. Its headquarters are 4/a de Donceles, 87, Ateneo Ceres, Mexico, D. F.

Cultivation of Quinin

The government through the agricultural department has applied to Ceylon and to Peru for a good quantity of seeds of different species of "cinchona," with the object of cultivating this useful plant in the warm regions of the country. Attempts have been made on other occasions to cultivate the quinin plant in the state of Veracruz, but even although it was found to thrive well there, its cultivation never was carried to a point where it would have commercial importance.

Infant Welfare in Yucatan

The municipality of Merida, Yucatan, recently organized a competitive baby show with certificates and money prizes. The show was a great success. The *Universal,* the leading Mexican daily, has organized on different occasions two competitive exhibitions of the kind.

Aid for the People of the Devastated Regions

The ladies of the Allied colonies here are still busily at work making garments to be sent to Europe to relieve the peoples freed from the yoke of the invader.

Donation

A number of persons contributed money to aid in the combating of the epidemic of influenza, among others, Mr. E. L. Doheny of New York, president of the Huasteca Petroleum Co., who donated 30,000 pesos for the purpose.

Vital Statistics

As a curiosity, I add the official record of the deaths over a certain period in a town in San Luis fifty years ago: Died a natural death, 1; died of grief, 5; died of fright, 2; died of disease, 2.

LIMA LETTER

Lima, Peru, Nov. 7, 1918.

Personal

The National Academy of Medicine has just resumed its labors with important discussions on the compulsory registration of tuberculosis and the sanitary improvement of Lima. The existing vacancies in its membership have been filled by the election of Drs. Carlos Monge, Ramon Ribeyro and Carlos Enrique Paz Soldan.

Sanitation of Lima

Congress has just passed the bill, which will soon become a law, on the sanitation of Lima. It includes rebuilding of the city sewers, provision for a new water supply, and street paving. The law contemplates the placing of a loan of $5,000,000, 70 per cent. of which will be offered in foreign countries, most probably in the United States. Proposals for these works will be requested from constructing firms, thus offering an excellent opportunity for American houses which might wish to invest money in Peruvian enterprises. Mr. Spalding, a civil engineer, is under contract with the city of Lima for the preparation of the necessary plans.

Febrile Epidemic

At present, Lima, Callao and the smaller towns in that vicinity, as likewise other cities in the country, are suffering an epidemic of catarrhal character, probably influenza, which has caused a great deal of sickness. The chief symptoms are a high fever (100.2 to 104 F.) with no initial chills, abundant expectoration, cough, nasopharyngeal catarrh, prostration, and nosebleeding on the third or fourth days coinciding with the subsidence of the fever and the bronchial cold that follows. The fever lasts only three or four days, is mild and only causes death when previous lesions existed among the infected persons. In order to avoid the spread of the disease, a number of measures have been adopted; as closing the schools, issuing popular pamphlets of instruction and the appointment of a special commission to perform bacteriologic examinations. The work of the commission has not been made public as yet, but it seems that the presence of a gram-positive diplococcus has been verified a number of times. The Academy of Medicine has also appointed a commission of investigation.

The Orphan Asylum

The Society of Public Welfare of Lima has begun the construction of an adequate orphan asylum for which contributions have already been received to the extent of $250,000. Steps are also being taken for the establishment of an indigent asylum.

PARIS LETTER

Paris, Nov. 21, 1918.

Etiology and Transmission of Trench Fever

At a recent meeting of the Académie de médecine, Dr. Strong read a report on this subject. Trench fever raged in some of the armies on the western front, causing a considerable morbidity. In order to secure information as to the development of the disease, it was considered necessary to investigate the mode or method of transmission. A commission appointed by the American Red Cross undertook this work, and conducted experiments on American soldiers which disclosed the method of transmission. Trench fever is not transmissible to animals. Of 103 experiments on men, infected by bites of lice or transmission by the blood, the urine or the sputum, the disease was produced in sixty-three. These experiments confirmed the belief that trench fever is a specific infectious disease. The causative organism is a nonfiltrable virus, present in the blood plasma; inoculating healthy persons with this plasma produces the disease. The disease is usually transmitted through the bites of lice. The virus may be found in the urine and in the sputum. These excretions should, therefore, always be sterilized and every effort should be made to protect the soldiers against the bites of lice.

A Ministry of Public Health

In the name of the Commission d'hygiène of the Chambre des Députés, M. Navarre, deputy of the département de la Seine, proposed the creation of a ministry of public health to coordinate and have control of all the public health services, civil and military hospitals, asylums, etc.

In Honor of the American Red Cross

M. Davison, president of the war committee of the American Red Cross, was received at the Hotel de Ville de Paris, the day following the signing of the armistice. The city authorities made it a festive occasion. Dr. Louis Mourier, undersecretary of state for the Service de Santé militaire, was present at the ceremony, accompanied by Maréchal Joffre. M. Chassaigne-Goyon, president of the Conseil municipal de Paris, addressing Mr. Davison, expressed deep gratitude for the miracles accomplished by the Red Cross, and for the generosity of countless Americans who had made these miracles possible.

Control of Radium

A decree has been published in the *Journal Officiel* organizing the control of the manufacture and distribution of radium and, in a general way, of all radio-active substances and luminous products derived from them. This Bureau des corps radioactifs, created in the ministère de l'armement, will have supervision of manufacture, importation and exportation. The consumption will be controlled by the office of the undersecretary of state for the Service de Santé militaire, and the geographic service of the army.

Death of Dr. Gaston Humbert

Dr. Gaston Humbert, assistant professor on the medical faculty of Paris, and surgeon to the hospitals, is dead.

Personal

At its last meeting the Académie de médecine elected to membership in the section de pathologie médicale, Dr. Charles Dopter, médecin principal of the army, professor of epidemiology in the Ecole d'application de médecine et de pharmacie militaires du Val-de-Grâce.

LONDON LETTER

London, Nov. 14, 1918.

Sir Auckland Geddes

In this country, unlike France, very few physicians enter Parliament, and much fewer attain a prominent position in the political world. However, there are two ministers in the present government who before they entered politics were qualified though not practicing physicians. Curiously, they were both lecturers on anatomy. Dr. Addison, the minister of reconstruction and former minister of munitions, was lecturer on anatomy at St. Bartholomew's Hospital before he entered Parliament as liberal member for the working class constituency in London. Sir Auckland Geddes, the minister of national service, graduated with the degree of M.D. at Edinburgh in 1906 and subsequently became professor of anatomy at the Royal College of Surgeons of Ireland and later at McGill University, Montreal, where he made a reputation as a biologist. He served in France during the war and attained the rank of brigadier-general. Unlike Dr. Addison, he was not a politician before he entered the government. The prime minister, Mr. Lloyd George, made a new departure when he formed his government by appointing ministers who were not politicians but experts in regard to the duties they had to take up. Sir Auckland Geddes' brother, Sir Eric Geddes, the first lord of the Admiralty, is another example. He was previously controller of the Admiralty. Sir Auckland Geddes has just been appointed president of the Local Government Board, the duties of which he will combine with those of his present duties of minister of national service. With the close of the war the latter duties must considerably diminish. It is thought that he will become the first minister of health, an office which, as foreshadowed in previous letters, is to be created. The results of the examination of the whole male population of military age by the ministry of national service has disclosed an enormous amount of physical unfitness in the population, only about one third being found fit for Grade 1. The new ministry of health will combine all the duties with regard to the health of the people that have been performed by many departments, with consequent waste of energy and want of cooperation.

Strike at an Irish Lunatic Asylum

More than 180 attendants at Ballinasloe Asylum went on strike from the institution at half an hour's notice, leaving about 1,500 lunatics unguarded. There were in the asylum at the time about 280 patients with suicidal and homicidal tendencies. The committee offered a 10 per cent. rise on prewar wages without the bonus, but this was refused. Fifty patients, several of the most dangerous type, escaped. After six hours' absence the staff was prevailed on by a priest to resume work. The resident magistrate on his own responsibility guaranteed the required wages.

Marriages

Walker Atwood Yeakle, Assistant Surgeon (j. g.), U. S. N. R. F., Norristown, Pa., on duty at Norfolk, Va., to Miss Elizabeth M. Wheeler of Towson, Maryland, November 27.

Hugh Quitman Allison, Lieut., M. C., U. S. Army, Grayville, Ill., to Miss Bessie Williams of Mount Carmel, Ill., at Belleville, Ill., February 8.

Aloysius James Larkin, Melvin, Ill., to Miss Florence Mary Garvy of Chicago, September 4.

Henry H. Seltzer, Washington, D. C., to Dr. Sarah L. Behm of Colorado, recently.

Deaths

Samuel Abbott Green, Boston; Harvard Medical School, 1854; aged 88; a member of the Massachusetts Medical Society; surgeon of the Second Massachusetts Militia in 1858; assistant surgeon, First Massachusetts Volunteers, and surgeon, Twenty-Fourth Massachusetts Volunteers, and brevetted lieutenant-colonel for gallant and distinguished services in the field during the Civil War; superintendent of the Boston Dispensary from 1865 to 1872; city physician of Boston from 1871 to 1881; mayor of Boston in 1882; a member of the board of experts appointed by Congress to investigate yellow fever in 1878; for thirty years an overseer of Harvard College; a trustee of the Peabody Education Fund since 1888; librarian and vice president of the Massachusetts Historical Society; author of many monographs on historical subjects; died in the Hotel Lennox, Boston, December 5.

Benjamin Troop Phillips, Menominee, Mich.; Rush Medical College, 1870; aged 78; a member of the Michigan State Medical Society; president of the Wisconsin State Medical Society in 1892; a veteran of the Civil War; chief surgeon of the Lumbermen's Provident Hospital and St. Joseph's Hospital; one of the founders and for a time professor of surgical anatomy and operative surgery on the cadaver in the Wisconsin College of Physicians and Surgeons, Milwaukee; local surgeon of the Chicago and Northwestern system since 1871; died at his home, November 29, from cerebral hemorrhage.

Howard Walter Beal, Major, M. C., U. S. Army ⊕ Worcester, Mass.; Harvard Medical School, 1898; aged 49; a member of the American Association of Genito-Urinary Surgeons, and American Urological Association; formerly Acting Assistant Surgeon, United States Army, surgeon to the out-patient department and cystoscopist to the Worcester Memorial Hospital, and cystoscopist to the Worcester City Hospital; who was injured by a shell fragment, while on duty with the American Expeditionary Forces in France, July 18, died from his wounds in Paris, two days later.

Stephen John Henry Reed ⊕ **Capt., M. C., U. S. Army,** Fultonville, N. Y.; Albany (N. Y.) Medical College, 1907; aged 37; for two terms coroner of Montgomery County; who went to France with the One Hundred and Thirtieth U. S. Infantry, in May last, and afterward was assigned to the One Hundred and Thirtieth Field Hospital, Sanitary Train No. 108; was killed in action at Hill No. 281, October 21, and buried in the military cemetery at Glorieux, France.

Died in the Service
IN FRANCE
Capt. Stephen J. H. Reed, M. C., U. S. Army, 1881-1918

Irvin Edmund Bennett, San Francisco; University of Boulder and Denver, 1889; Jefferson Medical College, 1891; at one time a member of the Medical Society of the State of California; a veteran of the Spanish-American War, in which he served in the Philippine Islands as captain of United States Volunteers; a member of the staff of the Southern Pacific Hospital; died, October 28, from influenza.

William Breinig Erdman ⊕ Macungie, Pa.; University of Pennsylvania, Philadelphia, 1860; aged 80; a member of the state legislature in 1881 and 1883; for more than fifty years a member and for many years president of the Macungie School Board; one of the organizers of the Lehigh County Medical Society; a specialist on diseases of the eye and ear; died at his home, November 30, from influenza.

Andrew B. Gloninger, Lebanon, Pa.; University of Pennsylvania, Philadelphia, 1883; aged 57; formerly chief surgeon of the Good Samaritan Hospital, and founder and chief surgeon of the Lebanon Sanatorium; surgeon of the Fourth Pennsylvania Infantry during the war with Spain; died in his office, December 3, from heart disease.

Albert Bellingraph Mason, Waycross, Ga.; Atlanta, Ga., College of Physicians and Surgeons, 1909; aged 31; a member of the Medical Association of Georgia and American Academy of Ophthalmology and Oto-Laryngology; a specialist on diseases of the eye, ear, nose and throat; died at his home, December 4, from pneumonia following influenza.

Died in the Service
IN FRANCE
Capt. James MacFarland, M. C., U. S. Army, 1887-1918
(See The Journal, last week, p. 2011)

Albert Hayden, Shellsburg, Wis.; Washington University, St. Louis, 1876; aged 67; a member of the State Medical Society of Wisconsin, and a charter member of the Lafayette County Medical Society; local surgeon of the St. Paul System for twenty-five years; died at his home, December 6, from cerebral hemorrhage.

William Thomas Murphy ⊕ **Lieut., M. C., U. S. Army,** Waukesha, Wis.; Wisconsin College of Physicians and Surgeons, Milwaukee, 1904; aged 38; on duty with the Three Hundred and Thirtieth Aero Squadron; died in a hospital in Grantham, England, November 2, from pneumonia following influenza.

Daniel MacNorton, Yorktown, Va. (license, Virginia, 1885); aged 63; a practitioner for forty years; first collector of customs for the port of Newport News, Va., and once a member of the Virginia state senate and house of representatives; died in the Dixie Hospital, Newport News, November 29.

Joseph S. Gentile, Chicago; Chicago College of Medicine and Surgery, 1913; aged 33; a member of the staff of the Columbus Extension Hospital; who was shot, December 14, by a patient whom he was called to attend; died in the Columbus Extension Hospital the following morning.

James Russell Stewart ⊕ Colorado Springs, Colo.; Johns Hopkins University, Baltimore, 1909; aged 36; secretary of the El Paso Medical Society from 1916 to 1918; a specialist in tuberculosis; died in a hospital in Colorado Springs, December 6, from pneumonia following influenza.

Amos Frank Baumann, Waterloo, Ont.; Trinity Medical College, Toronto, 1885; aged 61; for ten years medical officer of health of Waterloo; a medical director of the Dominion Life Insurance Company since its organization in 1889; died at his home, November 25, from heart disease.

Frank Edgar Simons, Canajoharie, N. Y.; Albany (N. Y.) Medical College, 1879; aged 67; a member of the Medical Society of the State of New York, and president of the Montgomery County Medical Society; died in Canajoharie, October 1, after an operation for prostatic abscess.

George Joseph Spencer, Chicago; University of Illinois, Chicago, 1908; aged 41; at one time a member of the Illinois State Medical Society; city physician of Chicago, in 1911; who was in government service in Albany, N. Y.; died in that city, December 6, from pneumonia.

Clyde Edward Prudden ⊕ **Major, M. C., U. S. Army,** Duluth, Minn.; Northwestern University Medical School, Chicago, 1909; aged 30; a specialist in obstetrics and gynecology; is reported in the *Official Bulletin* of December 2, to have died from disease in France.

Robert Armistead McLean, Berkeley, Calif.; University of California, Berkeley, and San Francisco, 1874; aged 67; at one time a member of the Medical Society of the State of California; emeritus professor of surgery in his alma mater; died at his home, December 4.

Robert Archibald Gray, Shreveport, La.; University of Louisville, Ky., 1853; aged 88; a member and at one time president of the Louisiana State Medical Association; surgeon in the Confederate Service during the Civil War; died at his home, November 25.

William Sarsfield Morriss ⊕ **Lieut., M. C., U. S. Army**, Fall River, Mass.; Harvard Medical School, 1915; aged 29; on duty at Camp Joseph B. Johnston, Jacksonville, Fla.; while on furlough, died at his home, October 11, from pneumonia following influenza.

Joseph Vincent Kelly ⊕ Philadelphia; Jefferson Medical College, 1868; aged 74; medical director of St. Mary's Hospital and visiting physician to St. Timothy's Hospital; who served in the Navy throughout the Civil War; died at his home, December 6.

Charles LeRoy Griswold, Nanticoke, Pa.; University of Pennsylvania, Philadelphia, 1907; aged 35; a member of the Medical Society of the State of Pennsylvania; died at the Nanticoke State Hospital, October 7, from pneumonia following influenza.

Clarence Howarth White ⊕ **Lieut., M. C., U. S. Army**, Cohoes, N. Y.; University of Michigan, Homeopathic Medical School, Ann Arbor, 1909; aged 30; is reported to have died in a military hospital in France, November 12, from pneumonia.

William H. Moore, Martinsdale, Mont.; St. Louis University, 1905; aged 40; a large ranch owner of Montana; formerly a specialist on diseases of the eye, ear, nose and throat; died in St. Peter's Hospital, Helena, Mont., December 1, from pneumonia.

James Malcolm McKibbon ⊕ **Capt., M. C., U. S. Army**, Buck Valley, Pa.; University of Pennsylvania, Philadelphia, 1899; aged 46; died in Mobile Hospital No. 4, France, October 23, from wounds received while on duty on the fighting line.

Thomas Lindsley Bradford, Philadelphia; Homeopathic Medical College of Philadelphia, 1869; aged 71; author of several books and monographs on hemeopathy; librarian of Hahnemann Medical College; died at his home, December 3.

Benjamin William Carlson ⊕ **Capt., M. C., U. S. Army**, Denver; University Medical College of Kansas City, Mo., 1903; aged 44; on duty at Kelly Field, South San Antonio, Texas; died at that post, November 20, from pneumonia.

William Frank Guilfoyle ⊕ **Lieut., M. C., U. S. Army**, Philadephia; University of Pennsylvania, Philadelphia, 1905; aged 36; on duty with Base Hospital No. 31 in France; after having been gassed, died, September 2, from exhaustion.

Joseph Augustine McGowan, Philadelphia; University of Pennsylvania, Philadelphia, 1899; aged 43; physician to the Church Dispensary Southwark; died at his home, September 7, from carcinoma of the glands of the neck and throat.

Porton Rivolo Bennett, Los Angeles; Bellevue Hospital Medical College, 1879; aged 75; at one time a member of the Medical Society of the State of California; died in Daytona, Fla., November 19, from locomotor ataxia.

William Preston Harden, Bushville, near Commerce, Ga.; Emory University, Atlanta, Ga., 1886; aged 52; a member of the Medical Association of Georgia; died at his home, November 13, from pneumonia following influenza.

John D. Gordon Smith, Zolfo, Fla.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1912; aged 30; a member of the Florida Medical Association; died at his home, October 15, from pneumonia following influenza.

Herbert Ewing Larkins, Charlotte, Tenn.; University of Nashville, Tenn., 1909; aged 40; a member of the Tennessee State Medical Association; died at his home, October 16, from bronchial pneumonia following influenza.

Thomas Tounge Perkins ⊕ Cliftondale, Mass.; Boston University, 1898; Harvard Medical School, 1901; aged 45; a specialist on diseases of the eye, ear, nose and throat; died at his home, December 6, from heart disease.

Herbert Conrad Goings ⊕ Matewan, W. Va.; University of Louisville, Ky., 1896; aged 42; for ten years owner of the Matewan Sanitarium; died at his home, October 14, from bronchial pneumonia following influenza.

L. F. Alfred Ouellet, Orwell, Vt.; Laval University, Quebec, 1894; aged 48; a member of the Vermont State Medical Society; died at his home, October 5, from bronchopneumonia.

Harvey Lasher Thorpe, ⊕ **Capt., M. C., U. S. Army**, Los Angeles; Rush Medical College, 1909; aged 36; who left California, for overseas, October 15, died at sea, November 4, from pneumonia, following influenza.

Romulus Falardeau, Montreal, Que.; Montreal School of Medicine and Surgery, 1908; aged 34; assistant to the surgical clinic of Laval University, and chief surgeon of the St. Justine Hospital; died, October 5.

Albert Marinius Larkin ⊕ **Lieut., M. C., U. S. Army**, Jasper, Minn.; University of Minnesota, Minneapolis, 1917; aged 29; is reported in the *Official Bulletin* of December 2, to have died from disease in France.

Allison Brown, Memphis Tenn.; Memphis Hospital Medical College, 1898; aged 46; at one time acting assistant surgeon, U. S. P. H. S., and on duty at Fort Stanton, N. M.; died at his home in Memphis, November 25.

William Johnston Calhoun ⊕ St. Charles, Ill.; University of Pittsburgh, 1891; aged 56; health officer of St. Charles; local surgeon of the Chicago, Great Western System; died at his home, December 9, from pneumonia.

Samuel Howard Monell, New York City; Bellevue Hospital Medical College, 1890; aged 61; a charter member of the Roentgen-Ray Society of the United States; died at his home, December 3, from pneumonia.

David Frank Hallett, McCool Junction, Neb.; Hahnemann Medical College, Chicago, 1878; aged 63; who was stricken with cerebral hemorrhage while making a professional call, November 23, died, November 30.

John Edward Williams ⊕ **Lieut., M. C., U. S. Army**, Roselle Park, N. J.; College of Physicians and Surgeons in the City of New York, 1913; aged 26; died in Chaumont, France, in August, from paratyphoid fever.

Eugene Van Valkenburgh Riker ⊕ Flint, Mich.; University of Michigan, Ann Arbor, 1887; aged 57; a specialist on diseases of the eye, ear, nose and throat; died at his home, November 25, from pneumonia.

Eliza F. Pettingill, Philadelphia; Womans Medical College of Philadelphia, 1864; aged 77; one of the promotors and visiting physician to the Women's Homeopathic Hospital; died at her home, December 2.

Leech Key Cracraft ⊕ **Lieut., M. C., U. S. Army**, Elm Grove, Wheeling, W. Va.; University of Virginia, Charlottesville, 1905; aged 36; died at his home, November 26, from pneumonia following influenza.

John N. Judy, Petersburg, W. Va. (license, West Virginia, 1901); aged 49; a member of the West Virginia State Medical Association; died at his home, October 27, from pneumonia following influenza.

William Hamilton Young, Starkville, N. Y.; Albany (N. Y.) Medical College, 1899; aged 39; D.P.H., McGill University, 1907; died at his home, October 14, from pneumonia following influenza.

George W. Caldwell, Waggoner, Ill. (license, years of practice, Illinois, 1877); aged 84; for sixty-three years a practitioner of Montgomery County, Ill.; died at his home, November 28.

Alexander Cairns, Coeur d'Alene, Idaho; St. Louis University, 1907; aged 49; who was awaiting commission in the Medical Corps, U. S. Army; died at his home, recently, from pneumonia.

Willoughby Dozier, Nashville, Tenn.; University of Tennessee, Nashville, 1877; aged 75; surgeon in the Confederate service throughout the Civil War; died at his home, November 8.

Edwin James Gravatt, Troy, N. Y.; New York University, New York City, 1891; aged 48; for six years coroner of Rensselaer County; died at his home, December 2, from pneumonia.

Alphonse F. Mercier, Montreal, Que.; Montreal School of Medicine and Surgery, 1894; aged 48; professor of the history of medicine in his alma mater; died, October 24.

Owen Harrison Foringer ⊕ Erie, Pa.; University of Pittsburgh, 1913; aged 32; a specialist in anesthesia; died at his home, October 20, from pneumonia following influenza.

George Elliott Merrick, Pittsburgh; College of Physicians and Surgeons, Baltimore, 1903; aged 45; died suddenly at Newcastle, Pa., November 5, from heart disease.

Henry James Mueller ⊕ Les Vegas, N. M.; Missouri Medical College, St. Louis, 1893; aged 49; died at his home, October 15, from pneumonia following influenza.

The Propaganda for Reform

IN THIS DEPARTMENT APPEAR REPORTS OF THE COUNCIL ON PHARMACY AND CHEMISTRY AND OF THE ASSOCIATION LABORATORY, TOGETHER WITH OTHER MATTER TENDING TO AID INTELLIGENT PRESCRIBING AND TO OPPOSE MEDICAL FRAUD ON THE PUBLIC AND ON THE PROFESSION

GOLDWATER ORDINANCE DEFEATED—ITS PRINCIPLE UPHELD

A Hollow Victory for the Nostrum Interests

On Dec. 31, 1914, the Department of Health of the City of New York revised the Sanitary Code so as to require that on and after Dec. 31, 1915, no proprietary or "patent medicine" should be sold in the city of New York until certain requirements had been met. The requirement was, in effect, that "the names of the ingredients of every such medicine to which the therapeutic effects claimed are attributed, and the names of all other ingredients except such as are physiologically inactive, shall be registered in the Department of Health." The ordinance did not apply to those proprietary or "patent medicines" which already gave the names—not quantities—of the ingredients on the label. This revision of the Sanitary Code—popularly known as the "Goldwater Ordinance"—was made, of course, in the interest of the public health. The ordinance left much to be desired from a public health standpoint, in that it did not require a quantitative formula, and further, in that it permitted an alternative of giving the public the facts. As THE JOURNAL pointed out at the time, if a layman desires to treat his own simple ailments —as he has a perfect right to—he has a right to demand the names and quantities of the drugs he is pouring down his throat.

In spite of its shortcomings, and in spite of the fact that the ordinance was not an onerous one, it was bitterly fought by the "patent medicine" interests. The fight was led by E. Fougera & Co., E. N. Crittenton Co., and H. Planten & Son. The case dragged its way through the courts and finally reached the Court of Appeals of the State of New York, which, a few weeks ago, handed down a decision in the matter. The decision was, in effect, that the ordinance had one real defect, although, as the court pointed out "one that amendment may correct," and that was that it did not protect the rights of dealers who had such preparations on hand at the time the ordinance went into effect. The court held, therefore, that in this regard, the Board of Health had exceeded the power delegated to it.

In discussing the objections raised by the Fougera concern to the ordinance, the Appellate Court said that most of them "we reject as inadequate." Quoting from the opinion handed down:

> "The argument is made that the ordinance is an arbitrary exercise of the power of government. We do not think so. Its purpose and effect are well within the limits of the police power. The purpose is the preservation of the public health and safety. . . . The form of protection is publicity. THERE MUST BE DISCLOSURE OF THE TRUTH TO RESPONSIBLE OFFICIALS WHO WILL PREVENT OR PUNISH THE SALE OF FRAUDULENT OR NOXIOUS COMPOUNDS. IF THAT IS NOT A LEGITIMATE PUBLIC AIM, WE ARE AT A LOSS TO KNOW WHERE ONE MAY BE FOUND. It is not important that the ordinance fails to compel disclosure to all the world. Laws are not invalid because they fall short of the maximum of attainable efficiency. Disclosure to all the world, as in Savage *v.* Jones, might make the protection more complete, but it would also make the hardship more severe. Something less, therefore, has been exacted. Disclosure is to be made to the health officers of the city, and to them only. If fraud or other wrong is discovered, then and then only exposure will result. 'NO MAN HAS A CONSTITUTIONAL RIGHT TO KEEP SECRET THE COMPOSITION OF SUBSTANCES WHICH HE SELLS TO THE PUBLIC AS ARTICLES OF FOOD.' IF THAT IS TRUE OF FOOD, IT IS EVEN MORE PLAINLY TRUE OF DRUGS. A danger exists, and the only question is whether the means of correction are appropriate. We cannot say that the means have no relation to the end.
>
> "The public health is safeguarded by disclosure to public officers charged by law with its protection. We are not called upon to approve the wisdom of the ordinance. We stop when we satisfy ourselves that it has a reasonable relation to the end to be attained." [Capitals and small capitals ours.—ED.]

Another argument made by the Fougera concern is that which has been made by the defenders of "patent medicine" interests before, namely, that, by requiring nostrum makers to publish their formula, they would be thus made to give evidence against themselves. THE JOURNAL has before commented on the moral status of a trade which cannot stand publicity—and admits it! In discussing this, the court said:

> "The sale of medicines is a business subject to governmental regulation. One who engages in it is not compelled by this ordinance to expose himself to punishment for any offense already committed. He is simply notified of the conditions upon which he may do business in the future. He makes his own choice. To such a situation, the privilege against self-accusation has no just application."

The objection made by the Fougera counsel, also, and one of the stock objections, it might be said, of the "patent medicine" fraternity, that prosecution for misstatement of therapeutic action would be the infliction of punishment for "mere error of opinion" was likewise dismissed by the court as inadequate. So, too, was the alleged objection that the ordinance would conflict with the federal constitution. On this the court's opinion was summed up in the statement:

> "The dominant scheme of the ordinance is disclosure of ingredients. That disclosure may be compelled, and the failure to make it punished, without trespassing upon the field which has been occupied by Congress."

From the foregoing it would seem that, while the "patent medicine" interests profess to see in the finding of the court a victory, the victory in fact, rests with the Law Department of the City of New York. The underlying principle of the ordinance was the right on the part of the city to compel disclosure of ingredients. That right the Appellate Court upholds. Further, practically every other objection to the ordinance that was raised by the expensive and impressive array of legal talent employed by the "patent medicine" interests, was dismissed by the Appellate Court as "inadequate"; finally the one weakness which made it necessary for the court to hold the ordinance void, is, as the court records, "one that amendment may correct."

WILL AMERICAN MUNICIPALITIES PROFIT BY EXPERIENCE?

To the Editor:—Now is the time for American small municipalities to rise and demand health protection and pay for it. Thousands of able, educated, experienced young medical officers from the Army, Navy and Public Health Service will soon be discharged or will leave by resignation. Give these young, able men a chance to work as paid health officers in each community of, say, 5,000 inhabitants and above. Pay them living salaries and make them independent from the start. Place them in groups under older officers as supervisors, and let the U. S. Public Health Service do the general supervision and direction of the work so that uniform and advanced procedure may be maintained. Establish suitable, perhaps small, but still well equipped laboratories in some centrally located larger city for bacteriologic and biologic work, and place an efficient officer in charge. Build hospitals.

Have an adequate staff of nurses on hand, not only to supervise the school hygiene, but also to visit and instruct families in their homes, and detect overcrowding in the slums of the city. Arrange self-sustaining, sanitary boarding houses for single men and women; protect the children from the evil influences of star boarders and the like. Segregate tuberculous subjects. Have a social welfare committee regularly appointed and managed by Red Cross staffs to teach the American way of clean living to the foreign born and to see that pure air and, in winter, heat is supplied the needy, and see that the children are properly clothed. Give the American public the benefit, the experience for which they had to pay so dearly. "Americanize the foreigner," by paying more attention to his welfare.

J. F. C. Luhan, Ph.G., M.D., New York.
Acting Assistant Surgeon, U. S. P. H. S.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

EXPERIMENTAL NATURE OF INFLUENZA VACCINES

To the Editor:—Can you give me anything definite as to the consensus of opinion of physicians in private practice with reference to the prophylactic and therapeutic vaccines in influenza? My own experience in several hundred cases seems to demonstrate their value, but our health officer has publicly announced that all preventive inoculations are useless. H. A. Vennema, M.D., Menominee, Mich.

Answer.—An editorial in The Journal, Oct. 26, 1918, after describing the two main types of vaccine now being used in this epidemic said:

> It will require many more carefully elaborated and controlled observations before anything definite may be learned in regard to the effect of these vaccines, and it is probably safe to say that nothing on which to rely in the future can be learned from the indiscriminate vaccination now going on. There is, therefore, no basis on which promise of protection from vaccines may be made. They may be harmless, and they may or may not be of preventive value.

In other words, at the time the editorial was written, the use of such vaccines was wholly in the experimental stage. Up to the present time there have been published, so far as we know, but two definite reports of adequately controlled experiments on the use of the vaccines. The first of these, that of Barnes (The Journal, December 7, p. 1899), concerned the use of the Leary vaccine, composed of strains of the influenza bacillus. This work indicated that the vaccine was not of prophylactic value. At the same time practically all of the recent bacteriologic work indicates that the influenza bacillus does not bear a causative relation to the present epidemic.

The second report, by G. W. McCoy, V. B. Murray and A. L. Teeter (The Journal, December 14, p. 1997), concerned a carefully controlled experiment on the use of a mixed vaccine similar to that brought out by Dr. E. C. Rosenow. The investigation indicates that this vaccine is not efficacious as a prophylactic against the present epidemic.

At this time it may be said that the use of vaccines in influenza is *at best* in the experimental stage, and that carefully controlled experiments exist which indicate that neither of the two main types of vaccines now offered to the profession are efficacious in preventing the spread of the present epidemic.

MARIHUANA, SYNONYM FOR CANNABIS INDICA

To the Editor:—I am told that on the Mexican border the natives make a cigaret out of a plant called Mara Huiwana. The Yaqui Indians are especially noted for this practice, and smoke the cigarets heavily, which results in producing hallucination and intoxication. Will you kindly give me some information concerning this plant? I at first thought it was loco weed, but am now positive that it is not.

F. F. Young, M.D., Covington, La.

Answer.—In The Journal, July 6, 1918, p. 60, in answer to an inquiry regarding this drug we said:

> We can find no reference to "maruhuana" or "marajuana" in available works dealing with drugs. According to Squire's "Companion to the British Pharmacopeia" (Edition 19, 1916) marihuana is a synonym in the Mexican Pharmacopeia for cannabis indica. The same name is also mentioned as a synonym for cannabis indica in "Plant Names," by A. B. Lyons (Edition 2, 1907).

Information received since suggests that the name may be applied to a stramonium plant, and that, as is generally the case, the same name is applied by the public to a number of plants. The symptoms mentioned in the query as being produced by smoking Mara Huiwana or marajuana are similar to those produced by the mescal plant, which was fully discussed in an editorial in The Journal, Jan. 15, 1916, p. 194.

CALCIUM HYPOCHLORITE

To the Editor:—Where can I buy a small quantity of calcium hypochlorite? I enclose clipping from The Journal.

George Martin, M.D., Elk Mound, Wis.

Answer.—The clipping enclosed entitled "Prophylactic Treatment of War Wounds" is an abstract of an article by H. Vincent, *Bulletin de l'Académie de médecine*, 1917, **77**, 136, which appeared in The Journal, March 31, 1917, p. 1009. Vincent gives this formula for the antiseptic powder:

Hypochlorite de chaux titrant 100 à 110 litres de Cl.......10 grammes
Acide borique officinal pulvérisé et bien sec..............90 grammes

The "hypochlorite de chaux titrant 100 à 110 litres de Cl" referred to in the foregoing formula corresponds to the chlorinated lime of the U. S. Pharmacopeia. This is essentially a mixture of calcium hypochlorite and calcium chlorid, and like the product referred to above is required to contain 30 per cent. of "available" chlorin. So far as we know, chemically pure calcium hypochlorite cannot be purchased.

HOME FOR AGED

To the Editor:—I wish to know if there is an endowed home for old men in the United States where care could be had for about $15 or $20 per week. I have a patient 77 years old who is in such condition that he needs a great deal of care and the family cannot pay the $25 per week that the hospitals charge. M.D.

Answer.—The Journal will forward replies to the inquirer.

Annual Congress on Medical Education and Licensure

The fifteenth annual conference of the Council on Medical Education will be held at the LaSalle Hotel, Chicago, Monday, March 3, 1919. On the following day, March 4, the Federation of State Medical Boards of the United States and the Association of American Medical Colleges will hold their annual meetings.

The discussions at this conference will be of problems arising from the world war, and will include the "Needs of Medical Education Revealed by the War" and such other topics as military training, hygiene, preventive medicine, condensed courses in premedical education, continuous sessions in medical schools, and other related topics. The discussions will be of interest from the standpoint of both colleges of arts and sciences and medical schools.

Among the speakers will be a number of prominent medical officers, presidents of universities and leaders in medical education.

Peking Union Medical School, Peking, China

The Peking Union Medical School was organized by a group of American and British missionary societies and began active teaching about 1906. It was supported by these societies until in 1915 the property was purchased for $200,000 by the Rockefeller Foundation. The control is now vested in the China Medical Board consisting of seven trustees appointed by the Rockefeller Foundation and six by the missionary societies formerly in full control. New buildings have been planned, several of which have already been completed, the curriculum has been revised, a new faculty has been selected, including ten all-time professors, and an ample endowment has been provided. The institution now offers a three year premedical course entrance to which is the completion of the middle school. This premedical course includes instruction in physics, chemistry, biology, English, Chinese and German. The work of the three years are said to correspond with the last year of the best high schools in the United States and the first two years of the best American universities.

The medical course will not begin until September, 1919. It will cover five years and will be followed by a sixth year to be spent by the student as an intern in a hospital. There will be no graduates under these higher standards, therefore, until 1925.

North Dakota July Examination

Dr. G. M. Williamson, secretary of the North Dakota State Board of Medical Examiners, reports the oral, practical and written examination held at Grand Forks, July 2-5, 1918. The examination covered 13 subjects and included 110 questions. An average of 75 per cent. was required to pass. Of the 3 candidates examined, 2 passed and 1 failed. Two candidates were licensed through reciprocity. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Rush Medical College	(1903)	75
John A. Creighton Medical College	(1913)	75.1
FAILED		
Chicago College of Medicine and Surgery	(1916)	62

College	Year Grad.	Reciprocity with
LICENSED THROUGH RECIPROCITY		
Illinois Medical College	(1905)	Indiana
University of Minnesota	(1915)	Minnesota

Connecticut November Examination

Dr. Charles A. Tuttle, secretary of the Connecticut Medical Examining Board, reports the practical and written examination held at New Haven, Nov. 12-13, 1918. The examination covered 7 subjects and included 70 questions. An average of 75 per cent. was required to pass. Of the 12 candidates examined, 9 passed and 3 failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
College of Physicians and Surgeons, Los Angeles	(1912)	75.6
George Washington University	(1917)	78.6
Howard University	(1912)	75.6
University of Maryland	(1917)	78
Tufts College Medical School	(1917)	80.3
Fordham University	(1918)	86.6
Long Island College Hospital	(1918)	80.7
University of Pennsylvania	(1918)	76
University of Rome	(1893)	77.3
FAILED		
Tufts College Medical School	(1918)	70.1, 72.1
Columbia University	(1915)	73.2

Iowa Reciprocity Report

Dr. G. H. Sumner, secretary of the Iowa State Board of Medical Examiners, reports that 1 candidate was licensed through reciprocity at the meeting held at Des Moines, Nov. 12, 1918. The following college was represented:

College	Year Grad.	Reciprocity with
LICENSED THROUGH RECIPROCITY		
Northwestern University	(1917)	Missouri

Book Notices

Psychology and the Day's Work. A Study in the Application of Psychology to Daily Life. By Edgar James Swift, Professor of Psychology and Education in Washington University. Cloth. Price, $2 net. Pp. 388. New York: Charles Scribner's Sons, 1918.

There is nothing more interesting than the human mind; and though we realize at times its influence on the most intimate details of our daily existence, we seldom stop to take account of the fact. As Swift says in his opening sentence, "Man's response to situations in the day's work is the measure of his efficiency." This book is not the typical dry as dust text on psychology, but all of the author's points are illustrated by anecdote from experience and from extensive literature which makes the book extraordinarily entertaining.

The first chapter, on organization for mental efficiency, gives attention incidentally to the various medical cults, the psychologic blunders of the German authorities, the penal system, the life of Al Jennings, the noted bandit, and of Patrick Henry, the noted lawyer, and to efficiency in public health. The second chapter concerns thinking and acting. This chapter describes the beginnings of numerous great inventions and the thought that led up to the discoveries. Especial attention is given to the habits of mind of the vivisectionists, and the author shows particularly the "power of empty words to cajole the human mind into placid assent in the conviction that it is thinking."

In the third chapter the author considers habit in the preparation for efficiency, discussing the theory of the formation of habit, the value of habit and its influence for perfect, as well as against perfect, efficiency. Special attention is drawn to the difficulties which great thinkers or discoverers have had in changing the point of view of contemporary men; for example, Harvey with the discovery of the circulation; Benjamin Franklin, with his work on electricity; Oliver Wendell Holmes, with puerperal fever; and incidentally, Galvani, Couvier, La Voisier, Young and Plenciz.

The fourth chapter, on the psychology of learning, relates mainly to the credulity of the human race, the teaching of animals, and the adoption of method, particularly the learning of the touch system of typewriting and the study of golf.

The fifth chapter is on fatigue and its psychology; the sixth, on curiosities of memory, in which especial attention is given to lightning calculators, what occurs in the mind during drowning, crystal gazing, hypnotism and also the training of the mind for permanent memory. Here especial attention is given also to the question of rapid, intensive or prolonged, careful study. The next chapters concern memory and its improvement and then testimony and rumor, the latter devoted especially to legal conditions. The ninth chapter, entitled "Our Varying Selves," is a psychologic study of personality, special attention being given to Kaiser Wilhelm; also to President Wilson, and to numerous characters from literature. The final chapter, on the physiology of digestion, describes the work of Pawlow, discusses the work of Carlson and then considers the general aspects of the influence of the mind on the stomach and vice versa.

The book contains numerous aphorisms which are worthy of especial consideration; for example:

> Experience is a filing-case from which man draws reports from his past life.
>
> Every experience is a scientific experiment reduced to its lowest terms.
>
> Unorganized knowledge is *only* wayward information, unfitted for application because incapable of being combined into a single impulse leading toward a definite conclusion.
>
> It is characteristic of the human mind to be attracted and impressed by the unusual or sensational and to fail to notice events that are daily occurrences.
>
> The basis of a good *memory* is to discover valid relations, such as those of time, place, similarity and dissimilarity, cause and effect.
>
> Experiments have proved that in general when the average man reports events or conversations from memory and conscientiously believes that he is telling the truth, about one fourth of his statements are incorrect.

The book is one that will pay every physician to read. Too many of us fail to appreciate the practical value of an understanding of the mental processes of the ordinary human being.

Medicolegal

Slight Evidence Suffices for Affirming Conviction of Manslaughter Through Malpractice

(State v. Young (N. J.), 103 Atl. R. 173)

The Court of Errors and Appeals of New Jersey, in affirming a judgment of the supreme court, which affirmed a judgment of conviction of the defendant of manslaughter for causing the death of a woman through malpractice in the performance of a surgical operation on her, she having died on the operating table, says that the argument, elaborately and forcefully addressed to the court of errors and appeals by counsel for the defendant on the merits of the case, could not properly be considered here, where the court deals exclusively with the legal questions presented by the record. It might very well be that the testimony tending to establish the guilt of the defendant was of such meager and attenuated character that, tested by a strict analysis, it was not clearly convincing of the guilt of the defendant; and even though it might appear to the court of errors and appeals that on a motion for a new trial in the trial court such a motion might properly prevail, nevertheless such a situation afforded no legal ground for disturbing the verdict in this case, so long as there was some testimony, no matter how slight, tending to support the finding of the jury. It is only when there is no testimony to support a verdict, and a motion is made for a direction of a verdict of not guilty, and such motion is refused, that such refusal may be properly assigned as error, reviewable here.

In the trial court one of the points made in behalf of the accused was that the removal of two parts of the smaller intestine together with the larger intestine could not possibly have been accomplished with the instruments that were alleged to have been used by the defendant in performing the operation. On the other hand, there was testimony tending to show that, in fact, there was no disturbance of the abdominal tract after death, and that when opened its contents were gone; and there was the testimony of every medical expert, except one physician, that they could not have been removed by the use of the instruments exhibited. The legitimate inference from all this would be that the contents were removed before death, and by some instruments other than those exhibited. On the other hand was the defendant's claim that, in fact, the removal of the contents had occurred after death. The jury evidently adopted the view that the contents were removed before death and by some instrument or instruments other than those exhibited. There was evidence on which to base such finding, and hence it would have been improper for the trial judge to charge, as requested, that there was no evidence whatever to show that any other instruments were used.

Insurer Cannot Be Sued for Malpractice

(Bowers v. Gates et al. (Mich.), 166 N. W. R. 880)

The Supreme Court of Michigan, in this action in tort for alleged malpractice brought against defendant Gates and an insurance company, reverses an order which denied a motion in the nature of a demurrer which the company made asking that the action be dismissed as to it. The court says that, as disclosed by his declaration, the sole tort charged by the plaintiff was that of malpractice inflicted on him by defendant Gates while professionally employed as his physician and surgeon to care for a fractured leg and ankle. The declaration contained two counts. The first one was against defendant Gates for malpractice, directed and exclusively devoted to his alleged lack of skill, malfeasance, and neglect while professionally attending the plaintiff as a physician, and the damaging consequences that the plaintiff experienced. The second count recited that the insurance company had by a described obligation in writing covering the period during which the plaintiff was under the treatment of defendant Gates contracted to hold the latter harmless against claims for damages, etc., wherefore the plaintiff was entitled to recover from the defendants his damages. The contract by virtue of which the plaintiff sought to make the company a party to this action was an ordinary one of indemnity insurance, headed "Physician's Liability Policy," by which the company contracted with defendant Gates to indemnify him against loss for liability imposed on him by law for damages on account of bodily injuries or death suffered by any person or persons in consequence of any malpractice, error or mistake made by him in the practice of his profession, or of any assistant aiding him in the administration of medical or surgical treatment, during the term of the policy. But, as to all the contractual obligations in the policy, the difficulty in seriously considering the plaintiff's theory was that he was in no sense a party to the contract or to the consideration for it. He was a stranger to it, and there was no privity of contract between him and the company issuing the policy. The insurer made no promises to him, did not know him in the transaction, and assumed no obligation for his benefit. Any right of action which might arise out of this engagement was vested in the person to whom and with whom the promise, or contract, was made. No statutory provision and nothing in the contract gave the plaintiff any right of action in tort, or otherwise, against the insurer of the alleged tort-feasor or wrong-doer. The law on that subject is elementary in principle. Nor did the company in fact or effect intervene and become a defendant in appearing, represented by the same counsel who appeared for defendant Gates, and taking on itself the burden of his defense pursuant to its contract with him.

Pneumatic Ambulatory Splint Malpractice

(Vander Wal v. Abbott & Wilcox et al. (Iowa), 167 N. W. R. 182)

The Supreme Court of Iowa in affirming, in this case "not to be officially reported," a judgment for damages for alleged malpractice by the defendants in the reduction and treatment of a fracture of the plaintiff's left leg, says that there was exacted, as the jury was told, that degree of knowledge, skill and care ordinarily had and exercised by the average of the profession in that or similar localities, having regard to the improvements and advances in their profession at the time. The contention of the plaintiff was that the defendants fell short of this measure of skill and care in several respects, and the sole issue presented was whether the evidence was such as to make out a case for the jury. The fracture was an impacted one at the base of the neck of the femur, and extended in an oblique line. It appeared to have extended from the greater trochanter down to and past the lesser trochanter, with a spiral fracture accompanying it below. A pneumatic ambulatory splint was made use of. The entire apparatus was approved by the experts who testified. The fault found was with the manner of the use of the apparatus, the adjustment thereof to the plaintiff's leg, and the attention given thereto. The plaintiff contended that the splint was not adjusted to the leg as it should have been, in that a bolt holding together the upper parts was left out when the bones were set, and the laces of the shoe were loosened, so that the splint did not hold the parts together, so as to be immovable. One of the defendants denied that the bolt was out when he called, but admitted to loosening the lace of the shoe, and asserted that he had drawn the buckle over the foot a notch tighter, which offset the change in lacing. The other defendant, on calling after about thirteen days' absence, remarked, according to the plaintiff, that the leg did not look good to him, and then inquired, "Who unloosened this strap?" and was told that it was done by his partner. Then he inquired, "Where is that screw?" and when told by the plaintiff that it was never in there, put his hand into his vest pocket, remarking, "Here it is; I forgot to put it in; . . . this is one of the essential things" to keep the leg stretched; and he put the bolt in with a screwdriver. The court sets out other evidence, but it says merely enough to show whether the bolt was in place, and whether the shoe was unlaced so as to leave the splint loose was an issue for the jury. And that body was warranted in finding from the evidence that leaving the bolt out or unlacing the shoe would have been improper practice. Evidence in behalf of the defendants tended to show that the instep was very high, and that there was a contraction of the tendon on the bottom of the foot which tended to draw the foot inward, and it rotated slightly inward. Another physician testified that if the splint had been properly adjusted, and kept adjusted, "you would not expect any disalinement of the foot"; and another one, that "when you have to refracture a limb, you do not usually get as good result." From this evidence the jury might have found that the defendants were negligent in omitting to adjust properly and keep adjusted the splint on the plaintiff's leg in that the bolt was omitted and the lace unfastened, thereby loosening the apparatus from the leg so as not to retain it in alinement, and that in consequence the leg was broken again, causing the plaintiff great pain and suffering. This pain and suffering furnished a basis for damages, even though the result may have been good. But there was evidence tending to show that there was a shortage of the left leg greater than ordinarily results from the setting of the fractured femur, for, though the physicians may have measured, the plaintiff stood in the presence of the jury, and with books under the short leg indicating its condition, the jury might have found from such demonstration that the leg was considerably more than 2 inches shorter than the other leg. That some of the facts may have been established by nonexpert testimony was not objectionable.

Not Barred from Testifying in Insanity Inquest

(In re Harmsen (Iowa), 167 N. W. R. 618)

The Supreme Court of Iowa, in affirming a judgment confirming a finding of the commissioners of insanity of Story County that the appellant was insane and a fit subject for custody and treatment in the hospital for the insane, holds that it was not error to permit a physician to testify to matters concerning which he acquired knowledge while the appellant was in his retreat and being treated by him. The court says that protection was sought by the appellant from this testimony under Section 4608 of the Code of 1897, prohibiting physicians and surgeons from giving testimony concerning matters of which they obtained information in that capacity. The inhibition relates to communications properly intrusted to the physician in his professional capacity, and necessary and proper to enable him to discharge the functions of his office according to the usual course of practice or discipline. This, however, does not disqualify a physician from testifying as to the mental condition of the patient whom he has attended as he observed it, even though he attended him professionally. The court adds that no communications seemed to have been made to this physician by the appellant as patient to physician. Nor does the court consider that another physician was barred from testifying, in whose case it appeared that he had never been called to treat the appellant professionally, but for twenty-five years had been a member of the commissioners of insanity, and was a member of the commissioners at the time the appellant was examined by the commissioners, and detailed what was said by the appellant at that time and what he observed at that time.

Employer Not Liable for Malpractice

(Congdon v. Louisiana Sawmill Company, Limited (La.), 78 So. R. 470)

The Supreme Court of Louisiana says that the plaintiff sued to recover $5,000 damages against the defendant, and, for cause of action, showed that, while he was in the employ of the defendant, he sought the medical aid of "the sawmill physician of said company" to remove a wart that was on his back, and which had been a source of annoyance to him for some time; that, in endeavoring to remove the wart, the physician applied an acid negligently, poured it on the plaintiff's naked back, and it circled around his body, consuming skin and flesh in its course; that the physician, through negligence or lack of proper knowledge and skill, utterly failed to relieve the plaintiff, etc. In affirming a judgment dismissing the plaintiff's suit at his costs, because he failed to state a cause of action in his petition, the court holds that when an employer employs a physician or surgeon of ordinary skill and ability to attend to his employees, and pays the physician from a fund collected from the employees and from which fund the employer derives no profit, he is not responsible in damages to an employee for mistakes of or malpractice by such physician, particularly, when it is not charged and proved that the employer was negligent in the selection of the physician. A petition for damages in such case should contain allegations of neglect on the part of the employer as to employing a competent physician, and that he derived some profit from the fund contributed by the employees to pay the physician. In the absence of such allegations, the petition discloses no cause of action.

Society Proceedings

COMING MEETINGS

Society of American Bacteriologists, Boston, Dec. 30-Jan. 1.

AMERICAN PUBLIC HEALTH ASSOCIATION

Forty-Sixth Annual Meeting, held in Chicago, Dec. 8-11, 1918

The President, DR. CHARLES J. HASTINGS, Toronto, in the Chair

The Etiology of Influenza

DR. WILLIAM H. PARK, New York: We concluded that whether or not the bacillus of influenza was the initiating cause of the present epidemic, it gave evidence that it has a marked pathogenic action, and this seemed to be sufficient reason for us to make a thorough trial of an influenza bacillus vaccine on the prevention, if not of the pandemic, at least of a number of the cases of infection with this bacillus.

The problem of producing immense quantities of vaccine, of determining the best dosage, the time for immunity, if any, to be established, of getting the proper controls in communities not yet infected, and above all of keeping good records and gathering and analyzing them, is one of the most important and staggering of problems.

We began the use of the influenza vaccine after the pandemic had already started, and some groups were not vaccinated until after the peak of the pandemic had been passed; so unless we have been able to get sufficient control cases, that is, presumably susceptible unvaccinated persons, exposed to the same degree, and observed at the same time as the vaccinated persons, we could arrive at no conclusion with regard to the efficiency of the vaccine. The reports from the use of the vaccine are being analyzed now, and it is already apparent that the majority of them are lacking in many essentials.

The intelligent use of the vaccine might have given us strong evidence in regard to the etiologic relationship of the influenza bacillus to the present pandemic; as it is, unless the finished reports prove to be better than they now promise, we must wait for such evidence as may be gathered from a serologic study of the various strains of the influenza bacillus isolated by us from the typical cases and from control cases.

DISCUSSION

DR. E. O. JORDAN, Chicago: In the present outbreak of influenza, conditions have been very different from those of which I have record. Instead of 8 or 9 per cent. of the deaths occurring between the ages of 20 and 40, over 60 per cent. have been of persons between the ages of 20 and 40. Where we find a similar bacteriologic picture in the true respiratory tract infections, it seems fair to suppose that neither the Pfeiffer bacillus, the pneumococcus nor the various varieties of streptococci are responsible alone for these outbreaks. We have in cases of pandemic influenza an infection with an unknown or unrecognized virus which increases the susceptibility of the individual normally to infection with the various pathogenic respiratory tract organisms, and superimposed on the initial infection we have a variety of secondary infections.

DR. J. W. NUZUM, Chicago: As regards the use of vaccines in influenza, we have seen some cases of the disease developing after the first injection of the vaccine, and we know of instances occurring after three injections of the vaccine; but we do not care to venture an opinion until we have been able to do considerable control work.

We have been impressed with the frequency of empyema in these cases. In our wards at the Cook County Hospital we have had from fifty to a hundred cases with empyema, and the predominating organism is the hemolytic streptococcus, a late secondary invader.

Dr. William H. Stokes, Baltimore: We have found the streptococcus and the pneumococcus, Types II and IV, in about 10 per cent. of the cases, both at necropsy and in the sputum; we also found the influenza bacillus.

Lieut.-Col. James G. Cummings, Washington, D. C.: In a series of 100 specimens, we have found only 12.4 per cent. of influenza bacilli. In 27.6 per cent. we have found the hemolytic streptococcus, in 90 per cent. Group IV pneumococci. We have found a low percentage of the fixed types of pneumococci. We have likewise found about 20 per cent. of *Micrococcus catarrhalis,* and a few staphylococci.

Dr. Ludvig Hektoen, Chicago: I think we must be dealing with a disease of unknown etiology, complicated by secondary infections of different kinds depending on local conditions in different parts of the country.

Dr. M. J. Rosenau, Boston: In the first twenty-six or more necropsies we recovered the influenza bacillus described by Pfeiffer in 83 per cent. of the cases examined. We also found it in pure cultures in the lungs of the fatal cases in a number of instances. In the remaining 70 per cent. fatal pneumococcic cases we failed to find the influenza bacillus. These patients died of croupous pneumonia due to Types II and IV of the pneumococcus, and in a few instances of the hemolytic streptococcus.

Dr. William C. Woodward, Boston: What has been the prevalence of the various kinds and strains of streptococci and pneumococci in the civil population prior to the appearance of influenza, and what has been the relative prevalence of these particular organisms among groups of persons in infected communities who have not had the disease?

Dr. William D. Stovall, Madison, Wis.: Unless a vaccine is made by growing the type in pure culture and mixing the types according to the organisms present, a vaccine of definite value probably cannot be obtained, because the mediums favorable to the growth of the pneumococcus cannot be favorable for everything. One type may overgrow the other. If they are grown in pure culture one may get definite effects from each type.

Dr. H. W. Hill, St. Paul: There is a prevalent belief among a great many people that relatively few tuberculous persons have escaped influenza. I should like to know the experience of the members in regard to tuberculosis and influenza.

Dr. J. O. Cobb, U. S. Public Health Service, Chicago: At Fort Stanton, N. M., they have had a very decided outbreak of influenza, with 149 cases out of 300 tuberculous patients, with 18 per cent. of deaths. The cases are identical with our present epidemic, and the patients died just as promptly at the government sanatoriums there as they did elsewhere.

Dr. William H. Park, New York: In the East we have had very little influenza complicated by empyema, but in different parts of the country there have been important and different secondary complicating organisms. In our own hospitals in the East we have only had one case of empyema in some sixty deaths.

As to the prevalence of the influenza bacillus in the cases prior to this outbreak over other organisms, I will say that the influenza bacillus has been present in the East in a great many cases in this epidemic. Every person with whooping cough seems to have the influenza bacillus.

Prophylactic Inoculation in Pneumonia and Influenza

Dr. Edward C. Rosenow, Rochester, Minn.: By the use of a properly prepared vaccine it is possible to afford a definite degree of protection for individuals, including pregnant women, during an epidemic of influenza. There is no noticeable increase in the number of cases immediately following the inoculations, and protection lasts for a period of at least six weeks. The favorable results from inoculations indicate that these so-called secondary invaders, which appear to have exalted and peculiar infecting powers, bear a close etiologic relation to epidemic influenza. This relation, however, may be in merely favoring the invasion of an unknown virus. Nearly all physicians report that the attacks of influenza are milder and of shorter duration, and that convalescence is more rapid in inoculated patients as compared with uninoculated individuals. The tendency of infection of the lower respiratory tract to develop pneumonia is noticeably less in the inoculated. According to the evidence at hand, the prophylactic vaccinations have conferred a decided immunity in pregnant women. This infection has proved very fatal among the uninoculated of this class.

DISCUSSION

Dr. George W. McCoy, Washington, D. C.: See the article on "The Failure of a Bacterial Vaccine as a Prophylactic Against Influenza," The Journal, Dec. 14, 1918, p. 1997.

Dr. Timothy Leary, Boston: In the treatment of influenza with an autogenous vaccine of mixed strains of influenza bacilli grown on human blood agar, we started on a local piece of work with our students and nurses in certain institutions which were receiving the first cases of influenza, and in which the incidence and mortality were very high. The results indicated definite value, and we proceeded from that to offer the vaccine for immunization to physicians and nurses generally. Again, the reports came back distinctly favorable, and if the agent is of definite value it seems to me that its use should be spread. We have as yet no definite information on which to draw final conclusions.

Dr. F. O. Tonney, Chicago: The ratio of influenza patients developing pneumonia in the unvaccinated of industrial groups studied was 1 in 21, while in the vaccinated it was 1 in 184. The ratio of influenza cases terminating fatally in the unvaccinated of the industrial groups in Chicago was 1 in 408, and in the completely vaccinated there were none in the 1,201 cases reported.

The influenza in vaccinated individuals occurred almost exclusively in those who had received one vaccination. No bronchopneumonias or deaths occurred in the vaccinated group after the second or third vaccination. The number of severe local reactions following vaccination was at the rate of 3 per thousand, and of severe constitutional reactions at the rate of 2 per thousand. These results are incomplete, but we offer them for what they may be worth.

Dr. J. J. Moore, Chicago: We have found hemolytic streptococci in the sputum, bronchi, lungs and especially, as Dr. Nuzum has said, from the pleural complications of this disease.

Dr. W. O. Sherman, Pittsburgh: At the Homestead plant, there were 1,687 of the employees who were not inoculated; 588 of those, or 30 per cent., contracted the disease. The number of deaths was forty-two, a percentage of 2.5. There were 5,964 who received one inoculation; of these, 213, or 3.5 per cent., developed the disease. There were nine deaths among these, or a percentage of 1.5; 5,222 received two inoculations, and 174 developed the disease, or a percentage of 3.2 with four deaths. The death rate was 0.08. There were 4,720 that received three inoculations; sixty-six of these, or a percentage of 1.4, contracted the disease. There were no deaths in those with three inoculations. There were 4,007 who received four inoculations at the one plant, and these data are accurate; 108, or 2.8 per cent., contracted the disease, and there were two deaths, giving a death rate percentage of 1.05.

Admiral E. R. Stitt, Washington, D. C.: We have been successful at the Naval Hospital, as they have in Boston, in treating postinfluenzal pneumonias with the serum of convalescents, and a very interesting thing in connection with trying out the serum of some of the convalescents is the potency of the serum therapeutically. It seemed to be almost a specific. I had the laboratory workers in the Naval School try out immunity reactions with this potent serum, which we knew was potent from treating different cases. There was no evidence that this serum possessed any antibodies for various strains of influenza bacilli.

Col. Victor C. Vaughan, Washington, D. C.: Before a barracks was built for the accommodation of our soldiers, Surgeon-General Gorgas understood thoroughly that the diseases we should have to deal with would be the respiratory diseases, as we call them. It is not generally known, but it is true that of all the diseases that General Gorgas had to deal with on the Canal Zone, neither malaria nor yellow fever was the most difficult. It was pneumonia. He knew how to prevent yellow fever and malaria, but he did not know how to take care of pneumonia. Three of us, with Surgeon-General Gorgas, went to the Secretary of War before there was a barracks built, and we told him that the diseases we should have to deal with would be pneumonia and kindred diseases, and we asked that sufficient space be provided in barracks for the men. The Secretary of War was highly appreciative of what we said and ordered it done. I want to say that with respect to crowding in our armies, I have come to realize that in the Army, especially in our camps, crowding in barracks is of very little importance compared with crowding under other conditions. When men are in the barracks and are asleep, they are not coughing, they are not sneezing, or doing anything of that kind. Most of them are asleep. It is when they are assembled in a large hall that trouble comes. At Camp Forest there were 9,000 people in a hall, for instance, and if every individual was perfectly upright, inclining his head neither forward nor backward, and the noses of these people were within 16 inches of one another, that being the greatest distance laterally, or 26 inches, with coughing and sneezing violently, you can readily understand what the condition of the atmosphere must have been, and it would have made but little difference if that building had had no roof and no walls to it. You can crowd men oudoors, and while they are outdoors you can crowd them just as much as when they are indoors; and I must say that this was something I had never thoroughly appreciated.

One word with reference to pneumonia, before we come to influenza: We had a splendid record for the first six months of the war. We had a death rate but little above that of the same age group at home; and thirteen out of the twenty-nine large cantonments had a death rate lower than the same age group at home. The Illinois division at Waco, Texas, had a death rate in the first six months of the war of less than one half of what occurred during the same time among the same age group in the city of Chicago, because they were selected men. You remember that the infectious diseases, especially the respiratory diseases, kill 40 or more per cent. men than women, and all these were men. So it is a wonderful record, and the same is true of New York, Pennsylvania, Ohio and various other organizations.

So far as pneumonia is concerned, during the first six months these facts seemed to be established so far as figures can establish anything: The city boy lived, the country boy died; the Northern boy lived, the Southern boy died. Whether these two are exactly the same or not, I do not know. Of course, the rural population is greater in the South.

Influenza—clinical influenza—struck our camps last February. It has been written up by Major Soper, and the report was published before the present epidemic of influenza came. It possessed all the clinical features of influenza that have existed this fall. At Camp Forest it came as it came on Camp Devens last fall, like a thunderbolt out of a clear sky, and prostrated a large number of people, and it was not followed by pneumonia. There were no deaths. Normally deaths did not increase as a result of it. We were on the outlook for influenza all the while. The first intimation we had in the Surgeon-General's Office of influenza's threatening this country came in August. A steamship on its way across the ocean from France was struck by influenza, and it was so badly hit that all of the seamen were prostrated and it had to put into Halifax before it could proceed to New York. We had that warning in August, and when this steamer reached New York it was thoroughly disinfected, and all this time this procedure was carried out at New York and Newport News: All troops ordered to France were sent to Hoboken and to Newport News and held in quarantine fourteen days. Every man was examined and his temperature taken once every day. No man with any elevation of temperature was allowed to go on board. As the men went on the boat in single file they were examined; the examinations were made daily, and if the men were found with elevation of temperature or signs of illness they were sent back home. We were looking for influenza of the virulent type at Newport News and New York, but influenza did not occur in New York, nor did it come into New York; it came in Boston. It may be a mere coincidence, there may be something more in it, but the influenza in 1899 entered the port of Boston. I think I can say with reasonable certainty that this influenza epidemic came into Boston Harbor, was landed at the Commonwealth Pier, struck Boston and Camp Devens only a few miles from Boston, spread from Camp Devens all over the country, and has traveled rapidly ever since. There cannot be any question as to how influenza travels; it travels on two legs, and man is the carrier.

I went to Camp Devens as soon as the epidemic was reported, and I might say that I thought my eyes would never see such horror as I saw there. I went through the Spanish-American War; I saw thousands and thousands of cases of typhoid fever, but I never had anything so depress me as the conditions that existed at Camp Devens.

Unfortunately, it has been almost impossible for us to study influenza. Why? Because men were dying from pneumonia, and we cannot spend the time to examine the blood of patients with influenza when so many people are dying from pneumonia. We are going to have influenza with us; it is not going to disappear very soon. I do not want to be a pessimist; I am always an optimist.

The second year of the epidemic of 1899 showed more deaths from influenza than the first year, and we are going to have the influenza epidemic for some time to come. Let us make a study of influenza as well as of pneumonia. Let us find out what is the cause of influenza. If I were asked to define influenza, I should say it is a disease of unknown origin, characterized by a marked leukopenia, and I am sorry that that has not been studied more carefully. As a result of the leukopenia the gateways of invasion are open, and any micro-organism that is lying around may invade the lungs if it is capable of growing and multiplying there.

So far as pneumonia is concerned, I am convinced that any micro-organism that will grow and multiply in the lungs may cause pneumonia. It is not the pneumococcus or streptococcus alone; it is not the Pfeiffer bacillus or the Friedländer bacillus alone. Any organism that may grow and multiply in the lungs will cause pneumonia. One man who studied pneumonia at Camp Devens came to the conclusion that the influenza and pneumonia were due to the Pfeiffer bacillus. Another man equally competent who studied it here at Camp Grant said it was due to a pneumococcus; another man studying it somewhere else said that it was due to the streptococcus, and so on. We can say, I think, with a great deal of certainty that influenza is very much like measles in this respect. It takes away resistance; and the organism that takes advantage of this is the prevailing organism in that community. We have streptococcus pneumonia; we have Friedländer's bacillus pneumonia, and so on. It has been observable all the way through this epidemic, and it has been mentioned in other epidemics of pneumonia following influenza, that it kills the strongest and most vigorous. Typhoid fever is more prevalent in men than in women and more prevalent in young women than among old men, because those people have the greatest range of activity. The man who is in a hospital, or the man who is on scout duty, is drinking water here and there. The greatest mortality was highest among the strongest and most vigorous because these have the greatest range of activity.

The death rate is higher in the civilian population between 20 and 40 years of age. Of course, in the Army we have only those between 20 and 45 years of age, and we have most susceptible material. We have been trying to find out what we could about this, and we calculate that these figures may not be exactly right. In Richmond, Va., for example, of the inhabitants between 20 and 40 years of age, there was one in six times as many deaths as had occurred. So we compared the death rate of all the inhabitants between 20 and 40 years of age with the death rate in the civilian population according to the number of those between 20 and 40 years of age. Here is the point: These diseases find suitable material between 20 and 40 years of age. I did not quite believe this, and there is an easier explanation than that. I think it is like typhoid fever, and that is, people between 20 and 40 years of age herd together, and on the whole the people who crowd together are the people between 20 and 40 years of age, either in military or civilian life. I want to exclude the possibility that there may be greater susceptibility at that age. Some say the older people have had it, and have asked why the younger people do not have it more. I will not go into that phase of the subject.

In the civilian population there are going to be recrudescences of it. Whether there are going to be recrudescences in the camps or not, I do not know. From a scientific standpoint, it is unfortunate that our camps are soon to be dissolved. We should like to know about this. We have been trying to distinguish between relapses and recurrences. We find a small number of people who have had influenza without pneumonia, who have thoroughly recovered, who have been apparently perfectly well from two to three weeks, and then they have come down again with all the original symptoms just as though they never had it. There is a larger number who think they have not entirely recovered. These were relapses, and we are trying to distinguish between recurrences and relapses. You cannot put any trust at all in the figures. In some places they call everything influenza if a man sneezes once or twice. In other cases they call it influenza pneumonia. In one camp there was an order that nothing should be called influenza unless the Pfeiffer bacillus was found, so we cannot tell how many cases existed in any camp in the United States. We can give the figures as they are put in, but we cannot tell what the percentage of influenza cases with pneumonia was. One thing that is certain is death. The diagnosis of death is certain. There is no question about that. We are figuring out that a certain percentage in this cantonment or this camp, etc., died.

So far as the prevention of the respiratory diseases is concerned, we do not know anything more than our ancestors knew a hundred years ago, and we may as well admit it. I say that in the face of the greatest pestilence that has ever struck our country we are just as ignorant as the Florentines were with the plague described in history. Now that the war is over and we have whipped the Hun, it devolves on the medical profession to work hard over the respiratory diseases, and see what we can do for them, and we must not stop until something of great value is done.

Dr. J. O. Cobb, Chicago: We should like to hear the incidence among the vaccinated in the Army with lipovaccines.

Col. Victor C. Vaughan, Washington, D. C.: We have tried with the greatest thoroughness the vaccines for influenza. We have used influenza vaccine in great quantities, all they could make in the Army Laboratory, and have used all that Dr. McCoy could spare, and also have used that which Dr. Park has furnished us from the New York laboratory, and I do not hesitate to say that it has not done one bit of good. Speaking on this point with the evidence of the Pfeiffer bacillus not being the cause of influenza, I can agree with those who have spoken. To me the evidence that the Pfeiffer bacillus is the cause of influenza is not at all convincing, because, in the first place, it is by no means constantly found in the influenza or the sequelae. In the second place, it is often even with greater frequency found in other diseases than it is in influenza. In the third place, influenza is characterized by a marked leukopenia, a matter that must be investigated more thoroughly. Injection of the Pfeiffer bacillus causes a leukocytosis, just the opposite, so I think the weight of evidence at least is against the Pfeiffer bacillus as being the cause of influenza. Besides, the first evidence that we had in the Army that virulent influenza was spreading through the world was the news we got in August that during the month of July influenza was exceedingly deadly in Germany. It was rife in Germany and caused a very high death rate. In July two conferences were called, one at Berlin and one at Munich, and Pfeiffer himself could not demonstrate in a large number of cases the Pfeiffer bacillus, and as you know, the general finding was a diplopneumococcus.

So far as vaccination against pneumonia is concerned, we have encouraging results, not, however, overwhelming, but encouraging results, concerning vaccine for pneumonia. At Camp Upton last year some 12,000 out of 30,000 men were vaccinated with lipovaccines of Types I, II and III. They were under observation six or eight weeks, after which they went overseas, and there was much less pneumonia among them. The report has been published by Major Cecil and Major Austin, and it was less during that six or eight weeks than it was among the unvaccinated. Since August, Major Cecil has vaccinated 80 per cent. of the troops at Camp Wheeler, about 15,000 or 16,000 troops altogether. He has vaccinated 80 per cent. of the troops that have been coming in all the time. They began at Wheeler with 4,000; then they came in bunches of several hundred. The latest report I had from Major Cecil, a day or two ago, was to the effect that there was practically the same number of cases of pneumonia among the vaccinated as among the unvaccinated; in other words, that there was just as much pneumonia among the 20 per cent. unvaccinated as there was among the 80 per cent. vaccinated. The pneumonias that did prevail were altogether of Type IV.

I agree that we should approach this subject with an open mind, ever ready to accept facts; but let us know they are facts before we accept them.

When it was decided to try vaccination, it was perfectly understood that this vaccination is not compulsory, and that every time an individual was vaccinated or had to be vaccinated he should be told that it is not compulsory. We have said to the men, "You can do as you please; we do not know whether it will protect you against influenza or pneumonia or not. It is an experiment." There is no compulsory vaccination at Camp Wheeler or anywhere else for pneumonia or influenza. There is compulsory vaccination for typhoid fever, but we are not justified in making any vaccination compulsory until we have overwhelming evidence of its value; and any man, whether he be in private life, in the Army or in the Public Health Service, who vaccinates anybody for pneumonia or for influenza and tells him that it is going to prevent the disease is not telling the truth.

With reference to the mask, I am strongly of the opinion that we have overestimated its value. That is nothing against the mask, however. When I went to Camp Devens they were not using the mask. I called the doctors together and I simply said, "Shall we use the mask or not? It is not compulsory." But I said, "Every doctor who took care of cases of pneumonic plague and did not wear a mask died from it, and every man who cared for pneumonic plague cases and didn't wear a mask did contract it. You can do as you please."

I am pretty certain, not convinced, that hand to mouth infection is of more importance than droplet infection. The most frequent way in which respiratory diseases are conveyed from one to the other is by hand to mouth. I feel that we should at least think of this in order to make an effort to prevent the spread of the disease.

Dr. B. Franklin Royer, Harrisburg, Pa.: Our experience has been that there are no dependable data thus far relative to the value of vaccines so that their use can be recommended. I could mention a dozen communities as examples where the epidemic of influenza was apparently snuffed out just as efficiently with the measures we used as in those communities where the vaccine was used.

Dr. G. H. Wood, Detroit: There have been some very severe reactions, some marked depressing effects from the use of vaccines in influenza. A safe rule to follow is not to give more than one half of the dose recommended at the beginning, then watch the patient, and increase the dose as the results warrant.

Dr. Edward C. Rosenow, Rochester, Minn: We cannot solve the problem of influenza or any other problem regarding the management of disease unless we try out experimentally certain methods. I have watched the occurrence of this disease through my section of the country, and for me to sit down quietly and do nothing was impossible. I stopped very vital work of other kinds to try and do something for my countrymen.

(To be continued)

AMERICAN ASSOCIATION FOR THE STUDY AND PREVENTION OF INFANT MORTALITY

Ninth Annual Meeting, held at Chicago, Dec. 5-7, 1918

The President, MRS. WILLIAM LOWELL PUTNAM, Boston, in the Chair

Public Health Service Program for the Nation Wide Control of Venereal Diseases

LIEUT.-COL. C. C. PIERCE, U. S. S. P. H. S., Washington, D. C.: Venereal disease is a problem which affects not only the soldier and the sailor, but also the civilian of today and tomorrow. Section 6 of the act to control venereal disease passed by Congress provides for the allotment to state boards of health of $1,000,000 each year for the two fiscal years beginning July 1, 1918, for the fight against venereal diseases. For the second of these two years the payment of the state's allotment is conditioned on the expenditure of a like amount by the state in the prevention of venereal diseases. For the first of these two years this condition is not imposed.

1. State boards or departments of health receiving their respective allotments have to agree to these cooperative measures: (*a*) Venereal diseases must be reported to the local health authorities in accordance with state regulations approved by the U. S. Public Health Service. (*b*) A penalty will be imposed on physicians or others required to report venereal infections for failure to do so. (*c*) Cases are to be investigated, so far as practicable, to discover and control the sources of infection. (*d*) The spread of venereal diseases should be declared unlawful. (*e*) Provisions are to be made for the control of infected persons that do not cooperate in protecting others from infection. (*f*) The travel of venereally infected persons within the state is to be controlled by state boards of health by definite regulations that will conform in general to the interstate regulations to be established. (*g*) Patients are to be given a printed circular of instructions informing them of the necessity of measures to prevent the spread of infection and of the importance of continuing treatment.

2. The Division of Venereal Diseases details to each of the various state boards of health an officer of the Public Health Service in uniform. His work is directed jointly by the Public Health Service and the state board of health. The general plan of work for the state bureau is: (*a*) The securing of reports of venereal infectives from physicians. (*b*) Suppressive measures, including the isolation and treatment in detention hospitals, and establishment of free clinics. (*c*) The extension of facilities for early diagnosis and treatment through laboratory facilities for exact diagnosis and scientific determination of conditions before patients are released as noninfectious. (*d*) Educational measures, which include informing the general public, as well as infected individuals, in regard to the nature and manner of spread of venereal diseases and measures to combat them. (*e*) Cooperation with local civil authorities in their efforts to suppress public and clandestine prostitution. (*f*) The keeping of accurate, detailed records of all the activities of the venereal disease work, copies to be forwarded to the U. S. Public Health Service.

3. Local or legislative funds that may be available shall be used by the state or city health authorities having jurisdiction for extension of the work.

4. In extension of the educational measures, the state's health authorities and its bureau of venereal diseases shall exert their efforts and influence for the organization of a state venereal disease committee for furthering the comprehensive plan for nation-wide venereal disease control.

5. The state health authorities shall take such measures as may be practicable for the purpose of securing such additional legislation as may be required for the development of control of the spread of venereal infections.

6. The state allotment shall be expended along general standard lines for all states and in accordance with an accounting system, to be forwarded by the interdepartmental social hygiene board, approximately thus: (*a*) For treatment of infected persons in hospitals, clinics and other institutions, including arsphenamin and other drugs, 50 per cent. of the allotment. (*b*) In carrying out educational measures, 20 per cent. (*c*) In carrying out repressive measures, 20 per cent. (*d*) In general administration and other activities of venereal disease control work, 10 per cent.

This distribution is provisional and subject to modification after conference and agreement between each state and the U. S. Public Health Service to best meet the needs of the particular state.

During the 609 clinic days represented, there was a total of 25,224 visits to the clinics, with an average daily attendance of 41.09 at each clinic. During the past month, 2,301 new cases were admitted. November 15, there were 11,149 cases remaining under treatment; 28,981 treatments were administered during the month; 2,777 doses of arsphenamin were administered to syphilitics. A total of 2,933 prostitutes were treated in the clinics, detention homes and jails. Of the prostitutes placed in detention during the month, 812, or 98.5 per cent., were found to be infected with venereal disease.

DISCUSSION

DR. JOHN M. DODSON, Chicago: The west Australian type of ordinance has been adopted in Chicago for the reporting of venereal diseases. The ordinance does not permit of reporting the name of the individual, but the case is reported by number by the physician, and it is made compulsory that he report it with the understanding that if the patient fails to keep himself under proper treatment, his name shall be reported and proper steps taken to see that he is kept under treatment until he is not a menace to the community.

DR. EDWARD P. DAVIS, Philadelphia: I desire to call attention to an apparent danger in the management of syphilitic cases. Since our knowledge of the cause of syphilis is now very evident, it was formerly considered that a woman giving birth to a syphilitic child could nurse the infant without infecting herself, and that the normal relationship of the nursing mother to the child could be maintained. It is now known that the reason a syphilitic infant does not infect the mother is that the mother is latently syphilitic. It is the duty of physicians and nurses having under observation women bearing syphilitic children to see to it that those women are kept under observation to prevent the development of syphilis.

Syphilis and Its Relation to Infant Mortality

DR. P. C. JEANS, St. Louis: When conception has taken place, the effect of maternal infection on the product of conception is dependent to a large extent on the duration of the pregnancy at the time of fetal infection. The infection of the germ cell, if such an event ever occurs, would preclude the possibility of its further development. The earlier in pregnancy the infection of the fetus takes place, the more likely is pregnancy to terminate in a dead or nonviable infant. The birth of a viable syphilitic infant signifies its infection late in pregnancy. The time at which fetal infection occurs is dependent on the activity of the infection in the mother, and this in turn is dependent to a large extent on the time that has elapsed since the onset of her infection. In many instances, in untreated mothers, pregnancies occurring ten years or more after the infection of the mother have resulted in the birth of nonsyphilitic children. A compilation of statistics shows that of 4,148 pregnancies in syphilitic families, 1,258, or 30 per cent., resulted in the death of the fetus at or before term. That this is more than three times greater than what might be considered the normal waste of life at this early age is shown by a similar study among the poorer class in both St. Louis and London, and including no obvious syphilis. In St. Louis, 9.9 per cent. of 886 pregnancies, and in London, 9.4 per cent. of 826 pregnancies resulted in the death of the fetus at or before term.

In St. Louis, clinical study was made of 854 infants of 1 year or under, and Wassermann reactions were made on all infants whose family history, personal history or examination gave any suspicion of syphilis. Of the 854 infants studied, forty-two, or 4.9 per cent., were found to be syphilitic. This figure represents the minimum in this group because it was not a complete Wassermann survey. In New York, Holt found 6.2 per cent. of positive Wassermann reactions among 161 infants under 2 years of age. Holt's series was selected to the extent that it contained no cases of clinical syphilis, but did contain a certain number of infants whose history or examination gave a suspicion of syphilis. Comisky reports 3.2 per cent. of positive Wassermann reactions in 1,074 new-born babies in Brooklyn. Because of the frequency of a negative Wassermann reaction in a syphilitic new-born baby, such a study, though interesting, does not represent the true incidence of syphilis. It would seem safe to assume an incidence of about 5 per cent. for syphilis in our infant population. A survey of about 300 syphilitic families in which there occurred 1,366 living births shows that 30 per cent. of these infants died at an early age.

From 10 to 20 per cent. of adult males and about 10 per cent. of married women are syphilitic, and a minimum of 10 per cent. of marriages involve a syphilitic individual. Seventy-five per cent. of all the offspring in a syphilitic family are infected. In a syphilitic family, 30 per cent. of the pregnancies terminate in death at or before term. Thirty per cent. of all infants born alive in a syphilitic family die in infancy, as compared to a normal rate of 15 per cent. in the same class. Probably 30 per cent. of clinically syphilitic infants die as a result of syphilis. Only 17 per cent. of all the pregnancies in syphilitic families result in living non-syphilitic children that survive the period of infancy. About 5 per cent. of our infant population is syphilitic. According to St. Louis vital statistics, 3.5 per cent. of all infant deaths are ascribed to syphilis.

The City Nurse as an Agent for the Prevention of Infant Mortality

Dr. Harriet L. Hartley, Philadelphia: In the matter of determining with some degree of accuracy the health of a given district or locality, we have no better or more intelligent surveyor than the city nurse. Her experience has brought her into contact with all kinds and conditions of men. Her method of approach to the keeper of the home, usually the mother, is one that breeds friendliness and confidence. An understanding of the true condition of the home and its inmates is arrived at from a standard point of view with a minimal waste of time. The city nurse, with her general training as a nurse, knows the earmarks of disease. As a public health nurse, she readily recognizes poverty, destitution and alcoholism. She can judge whether the family income is large enough or expended in such a way as to insure the proper amount of health and comfort to the family. Her connection with the board of health makes her an authorized sanitary inspector, and her general knowledge of the principles of housing and sanitation makes her a good judge of the conditions surrounding the young infant. She can intelligently observe the care of the food, the refrigerator, utensils, etc., which either intimately or remotely affect the health of the baby. She also brings into use her knowledge of ventilation, and readily determines whether the baby gets the proper ventilation to guard it against respiratory disease. In prenatal work the city nurse has no peer. The expectant mother is much more apt to confide in the nurse who gives advice about babies than she is any other type of health worker. The nurse often learns of the pregnancy early in its history, becomes the mother's friend and confidante, and leads her in the direction she should go.

Problems of Infant and Maternal Welfare in Rural Communities

Miss Katherine M. Olmsted, Chicago: The existence or development of a well and a broadly organized public health nursing section in every state health department is the first and the most important need in any movement for better care of our rural health conditions. The obligation of this department should be: 1. To stimulate local county demand for public health nursing service and secure public funds for maintenance of work in counties. 2. To provide well trained, competent nurses to meet the demand. 3. To coordinate and supervise the work of all the nurses throughout the state, much as is done with the county health officers now with a view to standardizing fundamentals and stimulate the tendency toward a higher type of public health nursing in rural sections.

1. The "Asthmatoid Wheeze": An Intrapulmonary Foreign Body Sign.—The presence or absence of the asthmatoid wheeze has been recorded by Jackson in sixty-two cases of intrabronchial foreign body, therefore he is inclined to regard this sign as of great value in many cases in which the foreign body is not opaque to the roentgen ray. He has called this new sign the asthmatoid wheeze because the sound is somewhat similar to the wheezing heard when the ear is placed to the open mouth of an asthmatic patient. The chief difference is that there is more or less association of the sounds of râles with the wheezing in asthma, while in the asthmatoid wheeze of the foreign-body case the sound is drier, when typically elicited, though it may be associated with more or less secretion, adding more or less of the sounds of bubbling. In a typical case the wheeze is much more marked after the coughing out of all secretion than before.

2. Demonstrating Tubercle Bacilli in the Urine.—In studying numerous specimens of urine for the presence of acid-fast organisms in various conditions of urogenital tuberculosis, Watson found that one important factor not previously given much attention is to use large amounts of urine, also to keep the specimen in the original container until the final sediment is obtained and to centrifugalize thoroughly.

3. Blood-Pressure and Kidney Function Findings in Orthostatic Albuminuria.—Five cases of orthostatic albuminuria, four of which are quite typical, were studied by Mason and Erickson especially as to pulse-pressure and kidney function when in different positions. They believe that the condition of orthostatic albuminuria is a general systemic disturbance, manifesting itself in faulty development, as shown by a general visceroptosis, a "drop heart," a generalized muscular and visceral atonia, which is known to be associated with varying degrees of vasomotor instability. The symptoms so commonly complained of, such as headache, lassitude, constipation and loss of weight, are the natural results of physical conditions. The increased lordosis that is usually present is regarded as a symptom due to the faulty muscular development and tone of the lumbar muscles. This exaggerated lordosis is well recognized in many muscular dystrophies and atrophies and in other conditions involving the lumbar and abdominal muscles.

The low pulse-pressure, in the opinion of the authors, is undoubtedly the cause of the albuminuria rather than a mechanical interference with the venous return from the kidneys. The interesting observation was made that the pulse-pressure can be lowered to almost the same degree by artificially producing lordosis while in the horizontal position as when erect. The albuminuria in all these cases varied inversely as the pulse-pressure, regardless of the position.

4. **Fractional Estimation of Stomach Contents.**—Hydrochloric acid medication is discussed by Crohn. The results following the therapeutic administration of acid are correlated and conclusions drawn as to the best method for the administration of this commonly employed medicinal agent. A study of the effects of acid on the stomach during digestion was made. Particular reference was paid to the changes in acid titer of the chyme both directly after the taking of the acid and during the subsequent cycle of digestive activity. In order to study the effect of a single dose of acid, cases of achylia gastrica or cases of pernicious anemia, with complete anacidity, were chosen. These cases were all uniform in presenting in the control fractional estimation tests a complete absence of free acid throughout digestion.

Crohn found that hydrochloric acid administered therapeutically to the fasting stomach promptly disappears from that organ, the last trace leaving within twenty-five minutes. The administration of acid before a meal exerted no influence on the acid secretion of the subsequent digestive cycle. Twenty minims of dilute hydrochloric acid failed to improve the condition of anacidity when given with a test meal. Forty minims of dilute hydrochloric acid gave a definite though moderate increase of acidity; this increase was temporary in duration, being usually limited to the short period directly after taking the medication. Ten minims of dilute hydrochloric acid administered every half-hour was a mild though efficient method of increasing total acidity during digestion. It was, however, insufficient to produce free acid at any time in the cycle of digestion.

It is conceded by Crohn that the method of administering repeated small doses of acid at frequent intervals is hardly a practical one for every-day clinical use. Where it is possible, however, the method should be adopted. For temporary usage it is often highly satisfactory. The customary method of administering hydrochloric acid as a single dose is, in most instances, insufficient to relieve the abnormal condition. Small single doses (5 to 20 minims dilute HCl) fail completely. Larger doses (25 to 40 minims) give better results, though the effects are but temporary, lasting usually for the first half hour only after administration. Administering small doses at frequent intervals, that is, every half—or better every quarter—hour, is more efficient for accomplishing the desired effect. The custom of giving acid before a meal has no advantages. The best results are seen when it is taken during the early part of the digestive cycle. The effect of acid so administered is purely a local chemical one. A resultant physiologic stimulation of the mucosa was never demonstrable from Crohn's experiments.

5. **Autoserotherapy in Tuberculous Pleurisy.**—Twenty-three cases of tuberculous pleural effusion were treated by Lyter by Gilbert's method (withdrawing a few cubic centimeters of the fluid from the chest and immediately injecting it into the subcutaneous tissues of the patient). Eight cases of the series underwent complete absorption within two weeks of the beginning of the treatment. Lyter believes that the absorption in these eight cases was more probably due to the natural physical phenomena than to the stimulating effect of the treatment. His results indicate not only that the treatment does not cause absorption, accompanied by diuresis, diaphoresis, rise of temperature and leukocytosis, but that in some cases it is not entirely devoid of deleterious effects on the tuberculous process in the lung. Lyter advises that the assertion that 80 per cent. of all tuberculous effusions undergo spontaneous absorption should be qualified, as the spontaneous absorption may not occur for months, depending most probably on the organization of the fibrinous covering of the pleura.

6. **Relation of Housing to Pulmonary Tuberculosis.**—Reckford analyzes the statistics which he has gathered together from the 116 Pennsylvania State Tuberculosis Dispensaries and describes details of procedure followed by that department of state activities.

9. **Influence of Radium Water Therapy on Creatinin and Uric Acid Metabolism in Chronic Arthritis.**—The authors had an opportunity to study the influence of radium on the metabolism of three patients with chronic arthropathies. These patients, who were on a purin-free, creatin-free diet, received, five times a day, 3 ounces of water impregnated with radium emanations, 20,000 Mache units in all. Only one definite change in the metabolism was observed: A slight increase in the rate of creatinin excretion with a somewhat increased variation in the day-to-day values, an effect which persisted for a time after discontinuing the radium treatment. The radium therapy had no influence on the uric acid content of the blood or on the rate of excretion of uric acid, total nitrogen or water.

10. **Anatomy of Coronary Arteries.**—Smith's study of injection specimens of dog and human hearts showed that there is an anastomosis between the branches of the right and left coronary arteries, which is, for the most part, by means of many small vessels, but distinctly numerous and large enough to functionate.

12. **Complement-Fixation in Hodgkin's and Allied Affections.**—*Kristjanson* claims that the complement-fixation test in Hodgkin's disease, using *Bacillus hodgkini*, preferably an autogenous culture, in the preparation of antigens, may give a positive, possibly a specific, reaction if the serum be obtained from the individual at the proper phase or stage of the disease. Experimentally, animals inoculated with *Bacillus hodgkini* give a specific positive complement fixation. Normal individuals and those suffering from syphilis and tuberculosis have not given this reaction in the limited number tested by the author.

13. **Hyperthyroidism in Recruit.**—Brooks expresses surprise at the large number of these cases which he has seen among recruits. The most striking feature of these cases in nearly every instance is tachycardia, rarely accompanied by arrhythmia even in cases of very marked degree, and polygraphic studies, except in instances complicated by other vascular conditions, show, aside from rapidity, few signs of abnormal action, except that in the same case there is, under varying conditions, usually great variation in the rate of systoles. Practically always the rate is increased by exercise, though there are exceptional cases in which, as in ordinary palpitation, exercise may slow the rate, especially when the attention is thereby distracted; but speed of action is even more constantly accelerated by excitement and disturbing emotional factors. Closely associated with tachycardia is an obvious and subjective throbbing of the superficial vessels, notably of the carotids, of the brachials and even of the femorals, while that of the aorta, in moderately thin persons, is also quite evident.

Under excitement, instead of an increase in systolic stroke, there is a fall in the stroking power, and this is much more evident in the medium sized vessels, as the smaller ones seem to contract while the larger vessels expand in their arc of pulsation. There is a wide area of apical pulsation, and so violent is this at times that an actual sucking sensation is produced on the palpating palm at the diastole. The heart sounds, because of their rapidity, are usually very difficult to analyze, but in many cases a soft systolic murmur is detected at the apex, and is transmitted at times with decreasing intensity toward the axilla. The marked alteration in the quality and occurrence of this murmur in the same case at different times is occasionally a striking diagnostic feature. Everything in the nature of graphic methods seems to indicate that these murmurs are functional and not organic in origin. The tachycardia is not controlled by digitalis, even when given in massive doses. The sedatives at times, notably the bromids, give marked relief in some instances, but are apparently without effect in others. Postural and emotional rest appear to be the most efficient measures of control. Cold applications to the precordium have little or no effect. Very closely associated with these definitely circulatory symptoms are those of dizziness and fainting. Commonly these attacks are accompanied either by a marked paling of the face or by a marked hyperemia. Such attacks are directly precipitated by exercise or by emotional stress, such as, for example, occurs during a physical examination.

Next to the tachycardia the manifestations which seem most striking to Brooks are numerous evidences of emotional instability, which is an invariable accompaniment of the disease. Irritability of temper, headaches and insomnia are almost constant, and during aggressive periods an intense feeling of fear, apprehension and terror, often quite beyond the control of the patient, is manifest. Outbursts of emotionalism are followed by a stage of great exhaustion, almost amounting to prostration, in which the patient may appear to be *in extremis*. The neurovascular instability is further shown by the *tache cérébrale*, by dermographia, by urticarial rashes and by the almost constant symptom of tremor, most marked in the hands; breathlessness at times, almost a dyspnea, is manifest, but without cyanosis or definite signs of asphyxia. The deep reflexes are excited, especially the knee jerks.

A considerable number of men give a history of ancestral goiter, particularly on the maternal side and sisters, less commonly brothers of the patients, commonly show similar goiter. There is also, in most instances, a familial history of nervous instability, of hysteria, insanity, perversions or of genius. Exophthalmos, which is so striking a feature of ordinary exophthalmic goiter, is present also in long-standing instances of this type. Not infrequently it develops very suddenly: it may be bilateral or monolateral or it may vary in either eye. During periods of excitement it is most evident, and as the tachycardia and emotionalism subside so also does the exophthalmos. In fact these men present, though in mild degree in some instances, all the cardial signs and symptoms of true exophthalmic goiter. Rest is the one factor which gives relief from symptoms.

25 Treatment of Neurosyphilis. J. B. Gooken.—p. 781.
26 Id. R. W. Harvey.—p. 785.

16. **Syphilis of Nervous System.**—A plea is made by Kaliski and Strauss for more intensive intravenous treatment of syphilitic diseases of the central nervous system. They claim to have proved that arsphenamin and immune bodies pass the barrier of the choroid plexus and appear in the spinal fluid after intravenous therapy. It is shown that after therapeutic doses of arsphenamin intravenously arsenic is found in the spinal fluid in greater concentration than can be effected by the introduction of arsphenamized serum or arsphenamin into the fluid. The intensive and prolonged use of arsphenamin intravenously combined with the exhibition of mercury and iodids has give the authors the best results in the treatment of syphilis of the nervous system. Intraspinal medication is of occasional and secondary value only. It may be tried in selected cases after intravenous and combined therapy have proved ineffectual in the event that the biologic reactions in the spinal fluid are positive. Reeducational measures are of great value in the treatment of ataxic patients. Forty-one cases are cited in detail.

20. **Differential Count in Syphilis.**—Blumberg claims that a high percentage of either small or large lymphocytes—or both—is present in almost every case of syphilis and that increase in lymphocytes may confirm the diagnosis of syphilis even when the blood Wassermann test presents a negative reaction, provided, that other conditions, usually accompanied by lymphocytosis, are absent.

24. **Intensive Form of Arsphenamin Therapy.**—In selected cases Hazen has been giving injections of arsphenamin at seventy-two hour intervals. He has given ninety-eight injections to twenty-two different patients, never giving less than three and several times as high as eight doses. There was not a single untoward result; while a number gave the usual reactions of nausea, vomiting, diarrhea and headache, there were no evidences of any increased intolerance toward the drug. In no instance was albumin demonstrated in the urine. None of the patients showed any jaundice and none lost any weight. The dose employed was 0.4 grams per 150 pounds of body weight. For such a dose 70 c.c. of distilled and double boiled water was used, and the sodium hydroxid solution was pure and fresh. All injections were given in the office and the patients allowed to go home immediately afterward. The clinical results were very good: lesions cleared up very shortly. Nineteen of the patients showed positive Wassermanns: in one instance a course of three injections failed to change this finding, but in all other instances, bar one, the Wassermann became negative with great promptness.

38 Use of Suprarenal Products in Addison's Disease. J. Daland.—p. 301.

33. **Thymus-Suprarenal-Pituitary Compensatory Syndrome.**—Seven cases are cited by Timme in which the chief complaint was great muscular fatigability, usually combined with headache referred to the frontal region and midway between the temples. Included in the history was frequently a statement of recent or concurrent rapid growth in height as well as of the extremities. The syndrome begins in youth, some years before puberty, and goes through its varying stages in about two decades. In its incipiency it presents largely the characteristics of the so-called status thymicolymphaticus, or status hypoplasticus of Bartels. The clinical history of these cases consists of a syndrome of thymus-suprarenal-pituitary combination, one Timme says frequently met with and its various stages are easy of recognition. The main characteristics of fatigability, low pressure, headache and growth are invariable components of the syndrome and depend on maladjustments of endocrine interactivity. Stabilization of the balance may be produced spontaneously providing the sella turcica may be made to accommodate a hyperactive hyperplastic pituitary gland. This is done presumably by erosion of the bony capsule of the gland. In cases of inability of such enlargement of the sella, the syndrome persists, but the symptoms may be alleviated by the feeding of pituitary extract continuously. In the course of the syndrome other glands may be brought into the complex and alter the picture somewhat, but these are vagaries and seemingly have no great determining effect on the course of events. Once recognized in any of the early stages, the further general progress of these cases can be prognosticated with a great degree of accuracy; and intervention, if necessary, can be undertaken with a large degree of success in the amelioration of the distressing symptoms.

34. **Is There a Thymic Hormone?**—Hoskins says that whatever be the real function of the thymus, certain it is that its

production of an internal secretion has not been proved. The evidence in favor of such a theory is but circumstantial at best and very meager. It is equally difficult to prove that the thymus does not produce a secretion.

37. Effect of Roentgen Ray on Response to Thyroid Stimulation.—Selected tadpoles were subjected to the action of roentgen rays in small amounts. Certain individuals were then treated with preparations of thyroid gland and the rate of their metamorphosis compared with the metamorphosis rate of (1) normal tadpoles, of (2) thyroid-fed tadpoles which had not been irradiated, and of (3) irradiated but not thyroid-fed tadpoles. The results of these experiments indicate that irradiation is without apparent effect on normal tadpoles, but determines a slight but distinct increase in the susceptibility of young tadpoles to thyroid stimulation.

Journal of Cancer Research, Baltimore

July, 1918, **3**, No. 3

39 *Experimental "Carcinomas" of Animals and Their Relation to True Malignant Tumors. F. D. Bullock and G. L. Rohdenburg.—p. 227.
40 Adenocarcinoma or Adenoma of Liver in a Mouse. S. Itami.—p. 275.
41 Hereditary Tumor in Fruit Fly, Drosophila. M. B. Stark.—p. 279.
42 *Biologic Treatment of Cancer. G. Fichera.—p. 303.

39. Experimental "Carcinomas" of Animals.—Bullock and Rohdenburg record the results of experiments on chronic irritation, undertaken with the view of reproducing, through means other than those employed by others, such lesions as they have described, in order to ascertain whether these might not be interpreted as hyperregenerative processes rather than as true carcinomas. The authors urge that extreme caution should be observed before reports of the production of cancer by artificial means are accepted. In irritation tumors, atypical proliferation and invasive growth, even when extensive, are held to be doubtful criteria on which to base a judgment of malignancy; and in the absence of continued growth after the action of the extrinsic irritant has ceased, experimental tumors should not be classed as malignant however close be the morphologic resemblance. It is a fact that the lesions reported by the various observers quoted are produced as readily in young as in old animals, and apparently do not possess the power of continuous growth on transplantation into animals of the same species, thus increasing the doubt regarding their malignant properties. All these facts Bullock and Rohdenburg believe point to the conclusion deduced from clinical observation, that age, organ specificity, and congenital defects play an important and, in many cases, a decisive rôle in the determination of the origin of cancer, and that irritation alone is an insufficient factor.

42. Biologic Treatment of Cancer.—Fichera reviews critically the work done during the past twenty years in the biologic treatment of cancer. He says that certain fundamental principles of treatment may be derived from such a review. Importance must be attributed to suitable dosage, to the proportion between the mass to be destroyed and the curative agent, and to the alternation of oncolytic stimulation with various histogenic products. Finally histogenic treatment adds to its indirect action on antiblastic organs an important direct action by reason of the oncolytic substances introduced. In developing the biologic treatment of tumors, Fichera is convinced that chemotherapy should be practiced by means of autolysates.

49. Epidemiology of Virulent Oriental Smallpox.—Riggs presents the results of his study of eight cases of smallpox occurring among a thoroughly vaccinated group of men. During the winter of 1917-1918, China suffered severely from epidemics of smallpox, diphtheria, scarlet fever and plague, and each of these diseases manifested an unusual degree of virulence. The eight men attacked were believed to be as fully protected against smallpox as is possible by means of vaccination. The interest in the situation, then, was in the result which might be expected to follow when a most virulent type of smallpox encounters a thoroughly vaccinated group of men.

In this instance, when more than 1,000 men were fully exposed to the most virulent epidemic that had visited the Chinese coast in many years, there resulted eight cases of smallpox representing five varieties of the disease. The ordinary variety of smallpox, that is, the discrete type of the disease, was not to be found in this series of eight cases. The virulent infection overcame whatever immunity had been established in the individuals by vaccination and resulted in one or another of five uncommon varieties of the disease. The discrete variety, the type that is ordinarily met with, was conspicuously absent.

The five varieties occurring in this epidemic were modified, abortive, confluent pustular hemorrhagic, and purpuric smallpox. Four of the eight cases were very mild and soon terminated in recovery without complications. With the remaining four, the the infection took on a violent form and ran a rapidly fatal course. Riggs urges that in the presence of a virulent epidemic of smallpox, at least three vaccinations in series of one week interval should be restored to, as this method seems to obtain a large number of "retardation" takes which in all probability have considerable immunizing power.

53. Midclavicular and Midsternal Lines for Recording Heart Outlines.—The authors' studies had for their object the question of the distance of the midclavicular line from the midsternal line, the relation of the left border of the heart to the midclavicular line, and the relation of the midclavicular line and the left border of the heart to the individual's height, weight and chest measurement. A group of normal men (307) was studied, irrespective of their nativity, physique and color, the only demand being that they must be free of any appreciable physical defect. These men were weighed, their height and chest were measured and, in addition, the distance from the midsternal to the midclavicular line was determined, the heart was percussed and the position of the left border expressed in centimeters distant from the median line. All methods were essentially clinical; no corroboration of the percussion was made orthodiagraphically. It was found that the position of the midclavicular line on the chest wall varies disproportionately with the height. Nor is the left border of the heart a fixed quantity, nor does it vary proportionately with the height. Thus a man of 5 feet 5 inches may have a heart 0.7 cm. larger than the man of 6 feet 2 inches. The largest hearts were seen in the man of 65 to 66 inches, and in these individuals the left border was over 1 cm. outside the left midclavicular line. As a matter of fact, in only two instances was the left border within the midclavicular line, namely, in the men of 69 and 74 inches.

Obviously this line is not a safe landmark, and equally obvious is the observation that no standard of comparison between the height and cardiac outline can be made. The only possible deduction is that irrespective of height and the midclavicular line, the distance of the left border from the median line is the only fair criterion, and, from the authors' figures, this distance is 9 to 10.5 cm. The midclavicular line is variable and also the size of the heart, but the left border in all but three instances (in the men of 150 to 159, 160 to 169, 200 to 209 pounds) was beyond the left midclavicular line, sometimes as far out as 1 cm.

54. **Emypema.**—Nims claims that much light is cast on the proper interpretation of the fluoroscopic image if the type of infection is known. Cases due to infection with *Streptococcus hemolyticus* are much more difficult of interpretation than are those with the standard types of pneumococcus, and more fatal. The diagnostic value of rolling the patient slightly from side to side for fluoroscopic study is strongly emphasized, for by this means only can the location of pus be determined in its anteroposterior relations.

56. **Meningitis Carrier.**—The authors cite the case of a soldier who was a carrier of meningitis. The organism was harbored in the nasopharynx exclusively. The persistence of the carrier condition was due to the localization of the organism in the adenoid tissue.

Neurological Bulletin, New York

57 *Temperature Reaction in Nervous Diseases. E. L. Cornell.—p. 335.

57. **Temperature Reaction in Nervous Diseases.**—The reaction to simultaneous cold and hot stimulation in twenty-two cases of syringomyelia, tabes dorsalis, multiple sclerosis, peripheral neuritis, and a case presenting a capsulothalamic syndrome was investigated by Cornell. It was found that patients suffering from syringomyelia, tabes dorsalis, multiple sclerosis, and the type of thalamic lesion presented in this study, generally show some disturbance in reactions to double thermal stimuli, whether or not evinced by ordinary clinical tests. There is a larger proportion than normal of single responses to double stimuli. There is more than a normal tendency, in many cases, to call temperatures of 41 degrees to 44 degrees C. or higher, warm instead of the usual hot. Reactions to double stimuli are in general more disturbed than reactions to single; and H-C responses more than C-H. C-H responses indicate the nearest approach to the normal reaction; they are the most frequent type in the least disturbed cases (with one exception); and they are nearest to normal in time for each individual. The differences between the different syndromes are sufficiently distinct to be suggestive, although there is some overlapping. Multiple sclerosis has a particularly clear-cut characteristic—a dissociation of the perception of doubleness. The double stimulation acts in such a way as to delay the perception of hot more often than that of cold.

66. **Reeducation of Injured Soldier.**—McKenzie says that the majority of the men who fill our war hospitals and convalescent homes must depend for most of their present treatment, and for their future efficiency, on the masseuse, the practitioner of electro and hydrotherapy, the physical instructor, and the teacher of vocational training. The course usually followed begins with preparation by heat, either wet or dry, or produced by electricity, on through the stimulation of nutrition by massage and passive movement, then to simple exercise taken voluntarily and eventually to skilled movements by gymnastics, games and handicrafts, and graduating into industrial training. The various steps of the treatment are described in detail.

7. **Treatment of Injuries to Crucial Ligaments.**—Generally speaking, Smith says, the immediate treatment of injuries to crucial ligaments should be conservative rather than operative. Recent injuries to the joint that show abnormal mobility should be roentgenographed as a routine. This will eliminate avulsion of the tibial spine. Where there is rupture of both crucials, due to lateral or posterior dislocation of the knee, the limb should be immobilized with the knee flexed to 20 degrees for at least three months, but faradism to the quadriceps and general massage with movements of the patella should be practiced daily. Good results have been reported from treatment by prolonged fixation of the joint. When the lesion is accompanied by a paralysis of one or both of the popliteal nerves due to stretching, postural and electrical treatment for the nerve injury must also be undertaken. Where there is a recent avulsion of the tibial spine, Smith advises to try the effect of immobilization of the knee in the fully extended position for twelve weeks, combined with massage and faradism, rather than to treat the case by primary operation and fixation of the detached ligament and its bony insertion. In cases of old standing, however, operative mea-

sures are indicated. The after-treatment of anterior crucial injuries can generally be undertaken by means of appliances worn for an indefinite period.

In the operative treatment of anterior crucial injuries, the following operations have been done at varying times, apart from those of immediate suture of the ligaments: (1) plication; (2) reefing; (3) wire loops; (4) silk ligament substitution; (5) fascial substitution. Smith's experience with these operations leads him to endorse only fascial substitution.

8. **Gunshot Wounds of Large Joints.**—Daw discusses this subject in all its aspects. He is convinced that improvement of mobility is more likely to be gained by slight movements followed by periods of rest, or by slow stretching of contracted parts—in other words, by gradual change of position —rather than by forcible movements through a large range. Open operations to obtain mobility, he thinks, are rarely advantageous, except in the case of the elbow joint, where they are usually satisfactory. He does not favor passive movements which he says have very limited value, and are often harmful. Active movements, however, especially those of normal use and occupation, Daw regards as being most valuable, often doing more to increase mobility than surgical measures.

9. **Treatment of Ununited Fractures.**—This paper deals with a series of sixty consecutive cases treated by Groves during the last two years, and refers almost entirely to gunshot injuries. Loss of substance was the most important factor in the production of nonunion. This cause accounted for thirty-four cases (56.6 per cent.). Necrosis, which is a common cause of delayed union, but a very rare cause of nonunion, was operative in three cases. In twenty-one cases nonunion was due to displacement of the main fragments. In two cases eburnation was the cause of nonunion. The series contains thirty-four cases of autogenous bone grafting. Of these, ten (29.4 per cent.) have been failures, five (14.7 per cent.) have been eventual successes in producing bone union after extrusion of the graft, and nineteen (55.8 per cent.) have been complete successes. In every one of the fifteen cases where success was not complete, the cause of failure was traced. The reasons for failure were: operation performed too early; scanty contact between the graft and its bed; a sliding graft; patient fell on his arm and broke the graft, bursting open the wound; the graft was laid in unhealthy bone which should have been removed; too complicated a procedure was adopted, and the patient died of shock; the humerus was not immobilized adequately, and the arm, hanging on the graft, broke the fixation; scars in front of the tibia were not sufficiently replaced by healthy tissue before grafting; periosteal flaps with thin bone scales adhering to them were turned down over the gap and produced only a thread of bone.

10. **Treatment of Disabilities of Upper Extremity.**—Dunn recommends nerve suture as the prime consideration in the treatment of disability of the joints of the upper extremity, and emphasizes the importance of tendon transplantation as the final operation to be undertaken in the treatment of disabilities of these joints. For it to be successful, the muscles must be strong and healthy and these will only be available if the joints they control have allowed of their free development.

11. **Primary Excision for Elbow-Joint Wounds.**—Eleven consecutive cases were recently treated at the Bristol orthopedic center after having had primary excision of the elbow joint performed at the front. Ten have flail elbows to a greater or lesser degree, and the uselessness of the limb is—if the length of time from the original wound be taken into account—in almost direct proportion to the amount of bone removed. As the amount of bone removed decreases so does the functional result improve. Moore says that extensive primary excision must result in a flail joint. Limited excision, however, is satisfactory. If the bone is comminuted, a muscle-fascia flap should be carried in to cover comminuted bone as is done in arthroplasty. The postoperative support of the forearm is essential, and rest is more important than early movement. Capsulorrhaphy in certain chosen cases of flail elbow has been effective.

13. **Injuries of Peripheral Nerves.**—The lesson which Souttar and Twining have learned best from their observation of 122 cases is that success in nerve surgery is a matter of organization. The investigation of the cases is so complex, the operations involve such unusual details of experience and technic and the after-treatment required is so tedious and varied, that only by means of an extensive organization can they all be satisfactorily carried out. The highest operative skill is of no use in the face of incompetent physicotherapy, while the most perfect physical treatment is powerless to remedy the mistakes of a clumsy surgeon. The authors plead for the concentration of all nerve cases in centers where they will have at their disposal the extensive material resources, the clinical experience, and the trained patience without which their recovery is a matter of chance; and they plead for routine and for simplicity in such a center.

A careful examination should be made in every case and recorded as soon as the patient is so far recovered as to enable it to be carried out. This examination is repeated once a month, and meanwhile he is every day under the close observation of the department until he leaves the hospital. After that an attempt is made to keep in contact with the man himself or his medical adviser. In operating, the surgeon should follow a simple and precise routine. He should have as clear and accurate a knowledge as is possible of the anatomy of the region, and the condition of the nerve which he may expect to find. He should have a clear idea of what he means to do, and he should do it in the simplest manner possible. The physical treatment of the case, before and after operation, should be based on a definite routine, although it should be directed to the special requirements of the patient, and should introduce all variety that is possible.

In the preoperative care of the patient the authors regard the whirlpool bath as the most powerful curative physical method at present at our disposal. It facilitates other methods, softening the limb for massage, and increasing its conductivity for electricity; it reduces pain; and it produces a feeling of wellbeing in the limb which stimulates the patient to those voluntary exertions without which no complete recovery can be obtained. A very important feature of the treatment is the great economy in massage effected. The duration of massage has been reduced from thirty to ten minutes, the actual process is easier and less laborious, while the results are in every way superior to those which could be obtained previously.

14. **Suture of Musculospiral Nerve.**—The three cases reported by Williams show the completeness with which motor recovery takes place after suture of the musculospiral nerve, and they emphasize the progressive downgrowth of the axis cylinder. The technic of the operation has in every case been quite simple, the nerve ends being brought together without any tension by a single catgut suture through the substance of the nerve. The line of suture was wrapped round the subcutaneous fat. Precautions were taken to prevent any tension on the union until a month had elapsed. In all cases the muscles paralyzed were relaxed by an extension splint.

26. **Membranous Colitis Treated with Enterococcus Vaccines.**—Fifteen cases of mucous or membranous colitis have been treated by Drew with great success by means of autogenous vaccines. The patients all exhibited most of the classical symptoms of this disease. All the patients with the exception of one, passed casts which examination showed to consist of a mucoid material, containing many goblet cells, leukocytes, and, in some cases, acicular crystals. The membrane in all cases swarmed with bacteria, of which the gram-positive forms predominated. In fourteen of the cases the enterococcus was observed together with *Streptococcus faecalis*. In no case could any evidence of agglutination be obtained with either organism, but in all cases a low opsonic index was obtained with the enterococcus. Complement fixation was obtained with four out of the six cases tested, using the enterococcus as an antigen. Drew found that many patients are extremely susceptible to the enterococcus, hence initial doses of vaccine of not more than 2 to 3 million cocci should be given. The treatment should be continued with gradually increasing doses till 500 million cocci can be injected without producing reaction.

29. **Neuroses and Psychoses of War.**—There appears to be general agreement on the value of the segregation of soldiers suffering from the neuroses of war, and Turner says three to four years' experience has justified the principle. It is essential that these patients, when segregated, should be under specially trained medical officers and that "an atmosphere of cure" should pervade the special hospital. The great value of segregation is that all patients may be studied individually and all agents determining causation, exaggeration of prolongation of symptoms may be sought out and eliminated. There is no evidence that in properly conducted hospitals these patients imitate each others' tremors or abnormal gaits, while it is well known that in general hospitals the eccentricities of conduct and behavior of the hysterical patients make them objects of curiosity and often of humor to the other patients. It has long been recognized that the sooner the patients are brought under skilled treatment the more rapid and satisfactory is the cure. By these means the symptoms which in the early stages are removable and "fluid" are prevented from becoming fixed and a "habit" established.

The French Military Medical Service recognized this early in the war and established neurologic centers in the zones of their armies. In consequence of the success attending the treatment of the war neuroses in these centers similar centers were established in the areas of the British armies in the winter of 1916-1917. A large number of cases of war neuroses in the early stages of their disability derive great benefit from a modified rest cure. In the later or "habit" stages a judicious combination of suitably directed psychotherapy and selected occupation, according to the mental and physical fitness of the soldier, gives the most satisfactory results. Occupation further supplies the best means of grading the soldier when the time arrives for his discharge from hospital to duty.

31. **Disabilities and Compensations Entailed by Reproductive Function of the Female.**—Lane speaks particularly of the thyroid. It is most closely associated with the sexual function in the female. The variations in the size of the thyroid afford clear confirmation of the preponderating influence of sex in the woman as compared to the part it plays in man. The thyroid enlarges periodically during the whole period of the woman's sexual life. This is more marked during a few days preceding menstruation, and continues while the period of sexual desire is at its height. After this the thyroid diminishes in size. This condition exists all through the sexual life of the woman. The enlargement of the thyroid is accentuated by intercourse and still more by pregnancy. The thyroid and the ovary would appear to go through associated stages of activity and rest.

Lane calls attention to the fact that one of the most marked features in advanced cases of chronic intestinal stasis in the woman is the total absence of sexual desire, it being replaced in many instances by a feeling of disgust for intercourse. Associated with this there is in this disease great wasting of the thyroid. This wasting is most conspicuous in the isthmus, which cannot be detected by the finger though the rings of the trachea can be accurately and clearly defined. The thyroid varies in size in the circumstances described in women whose hair is towy or red, as compared with the variations in women with dark hair. It alters with the intensity of the sexual appetite, which is a more marked feature in women of this colored hair than it is in the brunette. It is obviously the case that this type of woman resists the poisonous influences of chronic intestinal stasis with much more vigor and that she retains her sexual appetite up to a later stage in that disease than does her dark-haired sister.

Lane has noted that one of the most remarkable effects of freeing ileac effluent in chronic intestinal stasis by the removal of the colon is the rapid return of sexual desire, which may have been lost for some considerable time. Not only does it return to normal conditions, but in many cases it becomes manifestly exaggerated. In the female the toxins or organisms which are derived from the intestine in chronic intestinal stasis produce by their influence on the overstrained thyroid, directly through its blood supply or indirectly through its nerve supply, a far greater change than in man, and this occurs during the period of greatest sexual activity. Pregnancy affords the static woman with the prolapsed, angulated, and dilated gastro-intestinal tract, who exists in enormous numbers in the community, an opportunity of rehabilitating herself by reestablishing temporarily the normal flow of the intestinal contents, and so permitting her to store up in her body such a quantity of fat and muscle as will serve to retain her viscera in their correct positions and functions. How often, asks Lane, does one see a poor, thin, static virgin converted into a plump, healthy, happy mother by a pregnancy? How often is the surgeon called on to perform operations of a more or less mutilating character on the breasts and intestinal tract of women who, if they were able to perform the normal functions which they were born to carry out, would be restored to a state of health and happiness instead of leading lives of necessarily increasing invalidism and being a nuisance to themselves and to those with whom they are brought in contact?

52 *Deep Antisepsis. J. Voncken.—p. 437.
53 Epinephrin Test of Hyperthyroidism. J. De Laet.—p. 481.

47. **Surgical Shock.**—Starling is professor of physiology at London, and he concludes this report of his research on shock by emphasizing that shock is a state of hyperstimulation rather than of paralysis. Stimulants therefore are directly contraindicated, while morphin becomes the main reliance. There is general constriction of the blood vessels, and this is increased by the action of cold. The low pressure is due to the small amount of blood in actual circulation. The lacking blood must be replaced, and the acidosis from reduction of the alkaline reserve in blood and tissues must be combated with an alkaline fluid. Experience has shown the advantages for this of a 5 per cent. solution of gum acacia containing 2 per cent. of sodium bicarbonate. An injection of 500 c.c. of this solution should be given whenever an operation is to be done on a wounded man in shock.

48. **Latent Period in Shock.**—Baruch explains shock as the initial nervous shock, the effect of the traumatism. This sets in play a number of inhibitory actions, and these in turn entail profound modifications in important functions of the organism. Usually several hours elapse before they become manifest, and this latent period seems to be the preparation, the passage of the organic functions towards a deficiency, an upsetting of the balance, which permits complications of all kinds, and especially infection to get a foothold in the organism.

49. **Meningeal Reactions in Syphilis.**—Dujardin discusses the import for diagnosis and prognosis of the tension of the cerebrospinal fluid, its lymphocytosis, globulin and albumin content, and the Wassermann reaction in the fluid and in the blood. He assumes that the antibodies inducing the Wassermann reaction are derived from the blood, and that they pass into the fluid only when the meninges are pathologic. The normal meninges are not permeable for them, and hence the relative quantity of these antibodies in the fluid is an index of the degree of the involvement of the meninges. He determines this permeability index by ascertaining the minimal amounts of the fluid and of the serum which give the Wassermann reaction. If the serum gives it at a dilution of 1:10 and the fluid at 1:2, the former is thus five times stronger, and the permeability index is 1/5. The different forms of syphilitic nervous affections have special types of this index, and it is modified specifically by the effect of treatment. His extensive experience has demonstrated that with a zero index, every case of syphilis of the nervous system (not having presented paralysis or epilepsy), can be regarded as fit for military service provided the treatment can be kept up systematically, even if the Wassermann reaction in the blood is still positive. Men can be regarded as fit only for limited duty when the meningeal lesions persist (over 1.5 albumin) and the index persists after two courses of arsenical treatment. Also those who have had transient paralysis or epilepsy. Also those with incipient tabes, the reflexes abnormal, and the index persisting. Men should be discharged from the service who present syphilis of the nervous system with a permeability index persisting high (from 1/1 to 1/5) after two courses of arsenical treatment, and with more than ten units of antibodies in the blood and high albumin content in the spinal fluid.

51. **Treatment of Gonorrhea in Troops on Active Service.**—Van den Branden has no faith in the men treating themselves, but says that he has cured 65 per cent. of 410 acute cases and 53 per cent. of 232 chronic cases; 11 per cent. in each group are still under treatment, and 17 and 33 per cent. have been lost track of. The venereal morbidity in the Belgian army is probably higher than in other armies, as the men had no homes to go to when given furloughs, their homes and families being in the hands of the Germans. In treatment he applied the same measures as in peace times, with as scrupulous care, endoscopy, etc.

52. **Latest German Method of Antisepsis.**—The antiseptic is injected deep into the tissues all around the focus, making from seven to thirteen or more deep injections to encircle the focus. This is expected to form a barrier to wall in infection and keep it from spreading. The antiseptics preferred are derivatives of quinin: ethylhydrocuprein (optochin) and isoctylhydrocuprein (vuzine). The latter is extracted from a tropical plant *Remijia cuprea*, the Brazilian *quina do serra*. Another method by which this principle is applied is by expelling the blood from the limb and keeping it out with a tourniquet. Then 100 c.c. of a 1 per thousand or ten thousand solution of the antiseptic is injected into a vein, under considerable pressure. In half an hour or an hour the tourniquets are removed. Tuberculin has been injected in this way and other drugs, but serious by-effects have been observed, gangrene and pyemia with some war wounds. The addition of 0.1 gm. of lactic acid to the liter of the solution of the antiseptic prevents precipitation from the alkaline blood left in the veins. The favorable evolution of war wounds treated in this way has recently been ascribed to the biochemical properties of the quinin rather than to any direct antiseptic action, so that the principle, after all, Voncken says, is like that of Carrel's method.

54. **Microbes in the Air.**—THE JOURNAL has summarized some of Trillat's previous communications on the condensation of moisture on microbes floating in the air. He says here that this moisture condensed on the microbes serves as a culture medium as it dissolves gases that come in contact with it, especially the gases in expired air. The microbes expelled in droplets of spray in coughing and sneezing are preexisting microbes, but the microbes floating in the air in the condensed-moisture culture medium are liable to propagate and send forth swarms of newly born microbes to carry on the game. This invisible microbian mist condenses on cooler surfaces, as on the clothing when coming into a warm room from out of doors. The more vitiated the air, the more concentrated the culture medium formed by the moisture condensed on the microbes. A draft of air may sweep a cloud of these newly born microbes far from their primal source, and explain many otherwise mysterious cases of contagion. Or when the moisture condenses on the cooler surface of clothing this may provide the microbes with a still better culture medium from sweat or other matter on the clothing or hair. The propagation of the microbes may thus keep on indefinitely, and they may be spread broadcast wherever the person goes. Trillat's research has demonstrated the actual occurrence of all these phenomena with ordinary microbes, and naturally, he says, they must occur in a still more pronounced form the smaller the microbes, such as the filtrable causal agents of influenza.

55. **Suturing the Lips Together.**—Morestin expatiates on the advantages of cheilorrhaphy after an operation on one or both lips, or a burn. It averts cicatricial retraction and ensures as symmetrical a healing as conditions permit, the sound lip serving to balance and hold in a good position the lip that is being repaired. The patient can be fed easily from a catheter or nursing bottle introduced at the corners of the lips. His patients thus treated found no difficulty in spitting and smoking and none complained, while this cheilorrhaphy rendered possible certain autoplastic operations otherwise impossible to realize.

56. **Gas Embolism in Caisson Work.**—In the case described the workman was new at the task and the third day developed intense pain in his left thigh with other symptoms of caisson sickness, followed by a vast eschar in the left buttock,

corresponding to the course of the deep gluteal artery. Recovery followed under inhalation and subcutaneous injection of oxygen, with camphorated oil and strychnin, and excision of the devitalized tissue. It is the only instance Jean and Viguier know of in which the bubbles of gas were large enough to obstruct an artery of this size.

58 *Bone Grafts. Charbonnel.—p. 279.
59 Early Detection of Tuberculosis in Soldiers. Meslier.—p. 289.
60 Secondary Suture of War Wounds. Mongie.—p. 291.
61 *Mishaps with 914. Petges, Gratiot and Cottu.—p. 293.
62 *Enteropathies in Soldiers. Dargein.—p. 298.

58. **Free Bone Grafts.**—Charbonnel discusses the various methods for bridging the gap after loss of a section of the tibia, and describes the successful outcome in a case in which the fibula of the man's other leg was used for the graft. The fine results in this case justify, he thinks, the extensive application of this method of autografts with bone plus periosteum from the sound mate. The exact technic is described with illustrations. His case was subjected to a trying test, as at the fifth month the patient fell and fractured both the graft and the other bone in the leg. But they healed well and by the twentieth month radiography shows that the graft has not lost any of its opacity, while it is gripped firmly by callus coming from the stumps of the tibia. The graft itself does not seem to have participated in the callus production.

61. **Mishaps with Neo-Arsphenamin.**—Petges reports seven cases of severe therapeutic complications and one death among the 3,500 injections of this drug in the last seven months at an army skin and venereal center. The two cases with convulsions rapidly improved; the two with grave encephalomyelitis, and the two with the same plus meningitis also recovered but very slowly, and certain sequelae still persist. The graver cases were with recent infection and the primary dose was small. The one fatality occurred after the second injection, and the next gravest cases after the fifth and sixth injections. The paraplegia persisted for several months and in one case was accompanied with hematuria and gangrenous cystitis but clinical recovery followed in six months, except for slight paresis of the legs and Babinski sign. There had been preceding mercurial treatment only in one case as some of these patients were in the chancre stage. Neurofixation of the syphilis virus must be excluded, and as the technic cannot be incriminated, the disturbances must be ascribed to the drug itself. The patient should be warned of the possible danger from arsenical preparations, and he should assume some responsibility as well as the physician.

62. **War Enteropathies.**—Dargein emphasizes the necessity for explaining to the men the mechanism of the reflex sensations of which they may complain, and which are out of all proportion to the insignificant initial disturbance. He warns against measures liable to breed the "sincere pseudosick," the *pithiatiques de l'intestin.* An individual card or booklet for the pathologic data of each man would save a great deal of groping in the dark, and save many cases of purely functional disturbance from having the general health compromised by ill-advised therapeutic and dietetic measures.

73 Viscosity of the Blood in Heart Disease. M. Leconte.—p. 316.

64. **The Meninges in Malaria.**—Instead of being a disease of remote colonies, malaria is entering the current practice of physicians throughout France, as so many native and colonial soldiers have spread malaria germs broadcast. In this article a series of ten recent cases are reported in which meningism or meningitis dominated the clinical picture. The patients were all between 20 and 22 except one child of 4. The malarial parasite has never been found in the spinal fluid, so the meningeal disturbances must be of a toxic nature. This should be suspected with every meningeal reaction in persons known to have malaria or to have lived in a malaria infested region, and the blood should be examined.

65. **Partial Tetanus.**—Eleven days after a seton wound of the calf, intense pain, contracture and muscular spasms developed in the leg and persisted for a month without other symptoms. By the end of two months and a half, recovery was complete except for slight weakness in that leg. Intraspinal injection of 2 per cent. magnesium sulphate attenuated remarkably the pains and spasms, although it did not shorten the course of the disease.

67. **Aviator's Heart.**—Etienne and Lamy found in examining thirty aviators, including a number apparently healthy, that the left ventricle was enlarged, the apex rounding. This occurs early and persists, and is more pronounced the higher the flights. The hypertrophy keeps moderate, and there was associated dilatation of the right heart only in one instance. They warn aviators against useless feats, sudden changes of level, and abrupt rises and descents when such unnecessary strains on the circulation can be avoided. With care, the heart which has thus adapted itself to aviation will function normally.

68. **Opium in Heart Disease.**—Laubry and Esmein expatiate on the harmlessness of morphin and its success in many cases of heart disease. They regard the symptoms from cardiovascular affections as the result of physical rather than chemical forces, more dynamic and mechanical than toxic. There is no need with them to fear the specter of elimination of waste and danger from its brief partial suspension. The beneficial action of morphin on the vasomotor nerve centers can thus be utilized to the full. It usually reenforces the action of the usual heart tonics, and paves the way for the more slowly acting drugs to display greater efficacy. When the distress of angina pectoris persists under the usual measures, morphin should be injected and even repeated, warning the family of the gravity of the circumstances and that abstention may be graver than the injection. The same is true, they say, of acute edema of the lung, agreeing with Vaquez "that the injection of 0.01 or 0.02 gm. morphin is the best means to remedy the sudden danger which results from an attack of acute edema of the lung." Whatever the cause of the acute pulmonary edema, there occurs a sudden vasodilating excitation of the vessels in the lungs. In this sudden upset of the vasomotor balance, entailing a sudden profuse bronchopulmonary secretion, obstructing the air passages, why not utilize the drug which has an instantaneous sedative action on the vasomotor and secretory centers? Some are deterred from it by the fear of paralyzing some salutary secretion, especially renal secretion, and adding a drug poison to the unknown poisons from which the organism is already suffering. But in Vaquez' and the writers' experience they have always had cause for rejoicing that they had not been frightened away from its use. They always apply local or general venesection, with or without camphorated oil, but it was almost the constant impression that the subsidence of the secretory storm was the result of the sedative injection. In some cases of recurring pulmonary edema with aortic disease of different kinds, the morphin alone proved as effectual as when associated with venesection, when conditions prevented the latter. The same favorable result was obtained even in a case of sudden edema with high blood pressure and advanced kidney disease. Morphin is equally effectual also in relieving the mechanical, secretory and nervous disturbances entailed by paroxysmal hypertension, as in lead colics, sudden amaurosis, transient aphasia, asthmatiform attacks, and dyspnea without organic cause. Even in cases of albuminuria with high blood pressure and scanty urine, the attacks of dyspnea subsided under the morphin, the pulmonary and renal symptoms disappearing

together as a flood of urine was voided. The oliguria which seemed to contraindicate the morphin must have been itself the result of some spasm of the renal vessels. With permanent high tension, greater caution is necessary, but they have often relieved continuous dyspnea and insomnia in these patients with 0.2 gm. Dover's powder plus 0.1 gm. digitalis powder. They discuss further the indications for morphin in actual heart disease. With pulmonary embolism, congestion and acute edema, a local injection of morphin arrests the dyspnea and a Dover's powder maintains the salutary immobilization, and by keeping the entire organism quiet suppresses other factors liable to further hamper the heart. Paroxysmal tachycardia may also be relieved by the opiate when the pains and distress resemble those of angina pectoris. Among the formulas given is one in which 0.02 gm. each of caffein and pulverized opium are mixed with 0.2 gm. each of quinin sulphate and antipyrin. A cachet of this can be ordered every three hours, thus keeping the patient under the influence of mild opium medication for several days. To soothe attacks of pain, when instantaneous action is not imperative, they combine morphin with the rapidly diffusible vasomotor drug, trinitrin. Their formula calls for 0.06 gm. morphin hydrochlorid; 60 drops of a 1 per cent. alcoholic solution of trinitrin; 20 gm. distilled cherry laurel water, with plain distilled water q. s. to 100 gm. Two or three teaspoonfuls of this can be taken during the day.

69. **Juvenile Arrhythmia.**—Gallavardin describes six cases of total arrhythmia without valvular lesion. Some of these arrhythmias seem to cause no disturbance, but the outlook is much graver than with simple extrasystolic arrhythmia.

70. **Rupture of Heart Valve.**—In the man of 36 and woman of 46 the rupture occurred from shell concussion, without direct injury, but obesity or other predisposing cause was manifest.

71. **Slow Malignant Endocarditis.**—Debré describes the anemic, the pseudomalarial, nervous and rheumatismal forms among others, and mentions a psychic form. The streptococcus can usually be incriminated, but the pneumococcus, influenza bacillus, etc., may sometimes be responsible. In one case, in a child of 8, the typhoidal state and joint troubles were not accompanied by any appreciable symptoms on the part of the heart, and the endocarditis was only casually discovered. It proved fatal in less than five months. This type of endocarditis is most frequent in adolescents and young adults, and almost invariably there is an old history of acute articular rheumatism, with some recent infectious sore throat or other process in the mouth or in the female genitals. The skin manifestations are of primordial importance; purpura is more frequent, but the pathognomonic manifestation is a *transient* and painful erythematous eruption, minute red lumps appearing in successive waves on different regions of the skin. The pulpa of fingers and toes is a favorite site. The sudden appearance of this special eruption at the tip of the finger may suggest a coming felon. Periods of apyrexia may intervene, but the disease is always fatal in from six to twelve months.

72. **Serofibrinous Pericarditis.**—This affection should always suggest a tumor in the mediastinum. In a case described, necropsy revealed two tumors, and the pericarditis was symptomatic of the irritation from them.

78 *War Wounds of Nerves. Congress Report.—p. 549.
79 *Treatment of Gonorrhea. Congress Report.—p. 551.

74. Practically the same article was reviewed November 23, p. 1779.

75. **Tumors of Large Intestine.**—Pauchet has had very favorable experiences with resection of long segments of the large intestine for inflammatory and tuberculous tumors and for cancer. Once released from its moorings, the large intestine can be pulled around as readily as the small intestine. The ultimate outcome depends on the character of the cancer, and cancers of the large intestine are among the less virulent. By leaving a strip of the mesentery and the marginal artery the circulation is guarded, while the anatomy of the lymphatics of each segment of the colon allows the segment and its blood and lymph vessels to be removed in one block. He gives illustrations of the technics required for tumors at different points in the bowel. If there is occlusion he makes an artificial anus and waits a month before resecting the tumor. If the bowel is still permeable, for a tumor in the descending colon, he draws the loop out and makes a side-to-side anastomosis at once, or keeps the tumor loop thus exteriorized for a week, first suturing together, like two gun barrels, the legs of the loop just below the skin. After cutting off the projecting portion level with the skin, he waits a month before the final anastomosis of the stumps. A tumor in the sigmoid region he resects at once, and ties the upper stump on a rubber tube and invaginates this in the rectum by drawing down with forceps the lower end of the tube and out through the anus. The tube drops out *spontaneously* in about ten days. With a tumor in the transverse colon, he makes an end-to-end anastomosis after resection, fastening the point of junction to the abdominal wall. The worst that can happen is an abscess in the wall, with a briefly transient fistula.

76. **Secondary Endocarditis in Heart Disease.**—Lutembacher says that infectious endocarditis is responsible for the fatal outcome with valvular defects more often, probably, than asystoly. In such patients, any intervention on the veins requires the most minute asepsis, as the dilated cavities of the heart offer a peculiarly favorable site for location of an infectious process. If this process is of an abortive type, fever is its only manifestation. It keeps up irregularly for months, sometimes accompanied by chills and malaise, but its essential character is its extreme tenacity. The preexisting heart lesion does not seem to be modified, and the fever is ascribed usually to every cause but the right one. By the end of six or twelve months, however, the debility becomes extreme and death may ensue, even without embolism, a minute abscess in the wall the only necropsy finding. In the subacute form, septic thrombosis and embolism dominate the clinical picture. These are particularly redoubtable when it is a question of pregnancy or an operation or overexertion of any kind. It is by escaping such secondary infectious complications that some persons with serious valvular defects live to an advanced age while others with milder lesions die young. Treatment of these secondary infectious processes is discouraging. Intravenous injections of colloidal metals do no good, and he has never witnessed any benefit from specific serums and vaccines. Heart tonics had better be suspended as they lose their previous efficacy. This secondary infectious endocarditis is one of the main causes of what is called irreducible asystoly.

78. See Paris Letter, page 1759.

79. **Treatment of Gonorrhea.**—This was the leading question discussed at the French Urologic Congress in October, and the main addresses are summarized here. The reports bear on both military and civilian conditions. Janet related that abortive treatment is successful in about two third of the cases provided that it is begun within twelve hours after the first signs of a discharge. He has found antigonococcus vaccine beneficial in gonorrheal rheumatism, and he thinks a vaccine may yet serve in local treatment of the primary gonorrheal process when the technic is better worked out. Cathelin stated that, at most, the vaccine is useful only for the complications of gonorrhea and has no influence on the evolution of the urethritis itself. The *centre d'urologie* of the fifth district had 300 simple and 704 complication cases in the hospital; all the others were outpatients and 25,000 treatments were given. He urged standard uniform treatment with permanganate, but Hamonic extolled the advantages of iodin vapors pumped directly into the urethra from the iodin heated in an ampule. Le Fur warned that the seminal vesicles are involved more often than is generally recognized, and this explains return of symptoms, when the gonorrhea had been apparently entirely cured.

82 *Influenza in Children. H. Schultheiss.—p. 1467.
83 *Predetermination of Sex. P. Scheurer.—p. 1473.

80. **Recent Progress in Ophthalmology.**—Haab insists that the new legislation on industrial accidents and workmen's compensation makes it imperative for the general practitioner to be able to recognize and apply first treatment to injuries of the eyes. Intensive illumination from the side in examining the eye with the magnifying glass is imperative. A 150 candle power electric light is his preference; the ordinary street electric current suffices for this. A binocular magnifying glass or corneal microscope is extremely useful, especially when used with Gullstrand's Nernst *Spalt* light. Gullstrand's magnifying stereoscope for examination of the eye is also a great assistance in examinations. Another recent improvement is the use of light free from red rays, as Vogt advocates. In teaching ophthalmology Haab lays great stress on wax models and on demonstration microscopes. He keeps two of the latter where the students have constant and ready access to them, the specimens being turned by hand into the field, while they are locked in against injury. The Swiss government has appointed a woman artist to make wax models and casts for the clinics as needed. One model of the half of the head of a lad with tuberculosis of the cornea shows the suppurating fistula of the lacrimal sac and swelling of the glands in front of the ear—a typical case of Parinaud's conjunctivitis, in which tubercle bacilli of the bovine type were cultivated from the lesions. There was a history of a blow on the eye with a stable broom three months before the first symptoms. Under tuberculin treatment and diverting the secretions of the lacrimal gland into the nose, the cure is now practically complete fifteen months later. Catheter treatment of dacryocystitis seldom proves effectual.

Further progress in ophthalmology has been realized with roentgen treatment of cancer of the eyelids, but the greatest advance in recent years, he declares, is the treatment of gonorrhea of the eye by subcutaneous injection of 1 c.c. of a typhoid bacilli vaccine, containing 5 millions, the injection repeated the next day, or later. This method was advocated in 1917 by Szily and Sternberg who reported the complete cure in a few days of sixty-eight cases in adults. Haab tried it with considerable skepticism on a girl of 5 with violent inflammation of the eye. In two days the eye was free of secretions and cocci. In his five other cases the results were not so promptly apparent, but the cure was complete in all in two or three weeks, and injury of the cornea averted. The adult typhoid cultures, grown on agar, are washed off with saline and the suspension is brought to 200 c.c. It is then vibrated for half an hour, and 0.5 per cent. phenol added. More than two injections can be given at need. There is a brief febrile reaction; then in two or three days the inflammation in the eye subsides and the cocci disappear. The effect is less pronounced in ophthalmia neonatorum, but in one new-born child the severe gonorrheal ophthalmia had completely healed in two weeks, a result attainable otherwise only in from five to eight weeks. We know that the new-born do not react to vaccination as a rule. Genital gonorrhea in young and old does not seem to be affected by the typhoid vaccine.

81. **The Floating Tenth Rib.**—Frey is an anatomist, and he insists that the floating tenth rib is not pathologic but a normal phenomenon for a certain stage of phylogenetic development.

82. **Influenza in Children.**—Schultheiss states that while at first children seemed to escape influenza, the last few weeks have brought numbers of cases to the children's hospital, and there have been five deaths. The children did not succumb to respiratory disturbance so much as to the general toxic action of the infection, with the respiration typical of acidosis. Three children with whooping cough in one family all died, the blood in two showing 100,000 leukocytes with predominance of lymphocytes. In one case a child developed typical Landry's paralysis and in another paralysis of one arm, the eighth day. The paralysis in both gradually subsided but not completely.

83. **Predetermination of Sex.**—Scheurer analyzes the four main theories as to the predetermination of sex, those based on the assumption that the sex is preformed in the ovum or determined by the special structure of the spermatozoön, or by the battle of the sexes from the same or crossed heredity from the parents, or the assumption that the sex is determined by the age of the ovum at the day of conception. His conclusion is that the problem is still unsolved, but that the latter theory has much to sustain it. He describes Siegel's statistics in this line. (They were mentioned in The Journal, March 17, 1917, p. 883.) He found that in 180 cases in which the exact day of the husband's brief furlough was known and the date of the beginning of menstruation, 80 per cent. were boys of those children born when cohabitation had been within the first nine days after the beginning of menstruation; 80 per cent. were girls of those with cohabitation the fifteenth to the twenty-third day. Between these periods the sexes were about equally divided. From the twenty-fourth to the twenty-sixth day no conception occurred, and the twenty-seventh day only a total of five boys were born. If the proof can be produced that an ovum can actually survive menstruation, then Siegel's theory would have a basis. One observation on record sustains this, His' report of having found an unfecundated ovum in the human tube at the fifth day from the beginning of menstruation.

86 *Tuberculids in Children. A. Gismondi.—p. 635.

86. **Tuberculids in Diagnosis and Prognosis of Tuberculosis in Children.**—Gismondi discusses in particular the papulonecrotic type of tuberculids and their frequently grave prognosis. The literature cited confirms the unfavorable outlook with this form of tuberculids. They are generally found on the back, buttocks and limbs. In none of the cases described had there been preceding measles, although others have reported the development of these tuberculids after measles. In one case, however, there was a widespread eruption of tuberculids accompanying a tuberculous bronchopulmonary process following on scarlet fever. This child was 6 years old, with manifestations of inherited syphilis. The papulonecrotic tuberculids may be the only sign of tuberculosis in an infant or older child. By seeking them, many a puzzling diagnosis may be cleared up at once.

96 Tuberculosis of Male Genital Organs. E. Aievoli.—p. 794.

89. **Popliteal and Plantar-Cremaster Reflexes.**—As the subject lies prone and the popliteal space is tapped, certain physiologic reflexes occur. Roccavilla discusses the pathologic import of variations in the reflexes thus induced, and also in the variations in the cremaster reflex induced from the sole.

90. **Comparative Nutritive Value of Foodstuffs.**—Maurizi reviews recent investigations in this line, and reports personal research on rats. All tend to demonstrate that wheat and corn or their pure proteins have less nutritive value than eggs. It may be impossible to demonstrate this inferiority by a deficit in the nitrogen balance, but it becomes plainly manifest in the reduction in body weight.

Rivista Critica di Clinica Medica, Florence

Oct. 5, 1918, **19**. No. 40

97 *Pathology and Treatment of Asthma. R. Massalongo.—p. 469.

97. **Suprarenal-Pituitary Treatment of Asthma.**—Massalongo discusses the pathology of asthma as a perversion of the physiologic act of respiration. There is a centripetal and a centrifugal factor involved, and he regards the latter as of paramount importance while most clinicians incriminate almost exclusively the centripetal influence. He is convinced that the latter is merely the occasional cause. It is useful to get rid of this factor, but the primal factor is the inherited or acquired asthmogenic state of the medulla oblongata. It is a neurosis of the bulb and, in particular, of its respiratory center. There seems to be a close analogy between asthma and epilepsy. Persons with asthma have always proved to be neurotic, neuropathic, in his clinical experience. Treatment should aim to discover the source of the peripheral or internal centripetal irritation inciting the paroxysm, but the main point of attack should be the morbid sensitiveness of the asthmogenic center. The nervous system should be toned up by treatment as for neurasthenia, but the chief reliance should be on combined epinephrin and pituitary treatment. This, he says, has given marvelous results impossible to realize with either alone. He does not hesitate to call it an *infallibile metodo di cura dell' accesso astmatica*, and to say that his eight years of experience with it have fully determined its reliability. The dose found most effective was 0.0008 gm. of epinephrin (adrenalin) and 0.0004 gm. of pituitary extract (pituitrin), in solution in 1 c.c. injected subcutaneously. Even as little as 0.0002 gm. may prove effectual. The prompt action suggests that vasomotor paresis in the medulla oblongata may be the cause of the attack of asthma, as these substances overcome any such tendency at once. Their immediate efficacy further confirms the conception of the medulla as mainly responsible for the asthma.

100 Various Therapeutic Experiences. C. Ferreira.—p. 116.

98. **Diffusion of Filtrable Viruses Through Glycerin Vehicle.**—April 13, 1918, p. 1123, THE JOURNAL summarized Remlinger's statements in regard to the diffusion of rabies virus through the fluid in which tissues from rabid animals had been submerged. Bayma and Medeiros have had similar experiences with the glycerin in which cowpox material had been soaked, and they remark that the same probably will occur with any of the thirty ultramicroscopic viruses known at present. Photographs of children and of calves vaccinated with the glycerin thus left in contact with the cowpox pulp show typically fine vaccination pustules, sometimes even when the glycerin had been thus treated only for three days. The pustules in the children developed silently, without any local or general reaction; at most there was only a red border to the pustule. The cowpox virus seems to be more readily diffusible than rabies virus. None of the experiments gave negative results in any of the twenty of the five different series, while Remlinger had sixteen failures in his ninety animals with rabies virus and eleven died of septicemia. The same positive result was obtained in Bayma's eight children, there being scarcely any failures when there had been six days of contact. Parallel vaccinations with the usual whole vaccine showed constantly a more pronounced local reaction than with the glycerin alone, but in all the experiences, in the human and in animals, the typical pustule effect was unmistakable.

104 Some Clinical Notes. R. da Silva.—p. 243.

103. **Arsenical Treatment of Children by Way of the Rectum.**—Araujo reviews the extensive literature that has accumulated on the administration of arsphenamin preparations by enteroclysis. His list includes Oulmann and Wollheim's article in THE JOURNAL, Sept. 13, 1913, p. 867. They declared that the intrarectal route should be given the preference for children, and Araujo agrees with them, except that he regards mercury as the ideal remedy for syphilis in children. But when mercury fails, or exceptionally prompt action is necessary, or for other reasons arsphenamin is to be preferred, the enteroclysis method offers superior advantages for children. He reports four cases in detail, out of a much larger experience, emphasizing that he never witnessed any phenomena indicating a reaction, while the syphilitic lesions rapidly healed, even those in which spirochetes abounded. The results were invariably good, and the technic is the simplest possible. He used a 20 c.c. syringe and small Nélaton catheter. The bowels were emptied first, when possible, and the child constipated with paregoric, or 1 or 2 drops of laudanum were added to each injection. One female infant of 2 months was given a rectal injection of 0.03 gm. of Billon's 914 in 10 c.c. of distilled water, with 1 drop of laudanum. The injection was retained ten hours. Six days later another injection was given, which was retained only half an hour; two days later the injection was repeated with a dose of 0.08, retained for twelve hours. Five more injections were given, the last three with 0.10. Notwithstanding these large doses, there was never any appreciable reaction, and by the fourth, marked improvement was apparent, the papulous syphilids and patches in mouth and around the anus and vagina having completely retrogressed. The children were given usually about six intrarectal injections in doses of from 0.05 to 0.10 gm. at five or eight day intervals. The injection was generally retained from six to eight hours.

105 *Symposium on Ambard's Constant. V. Ruiz, L. Razetti, A. Benchetrit and J. B. Ascanio.—p. 187.

105. **Ambard's Ureosecretory Constant.**—Razetti laments that to date we have no reliable index of whether the liver and kidneys are able or not to stand general anesthesia. This can be estimated to date only by the comparison of the clinical data. Biologic chemistry has not given us yet the reliable guide which the surgeons are clamoring for. Even Ambard's constant has not proved to be the longed for practical guide in this line, whatever its usefulness otherwise. Benchetrit related that he has dropped the Ambard formula as its practical value does not compensate for the complicated technic required, especially, he adds, as the training of medical students in mathematics is in inverse proportion to the square root of the necessities of modern medicine—to parody Ambard's law. But from the purely scientific standpoint, he lauds the discovery of Ambard's laws as a gigantic progress, lifting medicine from empiricism toward the high station of an exact science.

106 *Stab Wound of Spinal Cord. E. Montaña and M. Rueda.—p. 623.
107 *Paraurethral Passages. R. Zapata.—p. 644.

106. **Stab Wound of Spinal Cord.**—Montaña and Rueda comment on a case of compression of the spinal cord by a fractured vertebra with partial section of the cord. The operation was restricted to lifting up the compressing lamina with probe and fingers, and clearing out sequesters and clots from below, leaving a rubber drain tube. Relief was immediate and recovery followed, but certain sequelae suggest that it would have been better to perform laminectomy at the time. They remark, however, that this is perhaps the first case of recovery after such a serious injury of the spinal cord, notwithstanding the timid and simply exploratory operation. The symptoms indicated that the right posterior roots and cords had been severed, along with the direct and crossed pyramidal tracts of the same side.

107. **Para-Urethral Passages.**—Zapata refers to the diverticuli or the passages from infected glands which are found opening into the urethra in gonorheal urethritis. They must be treated by catheterizing the minute passage, massaging the gland over a straight Beniqué, following with injection of some modifying substance such as silver nitrate or iodin. If these measures fail, the passage must be cut open its entire length.

112 *Medical Ethics. N. A. Rojas.—p. 491.

108. **Abdominal Pain in Diagnosis.**—In the case described the young woman for about eight months had been having digestive disturbance, constantly growing more pronounced and finally accompanied by intense pain in the epigastrium, not radiating, and not constant, sometimes soothed and at other times aggravated by eating, occurring at times before and at other times after eating. Occasional vomiting but no blood in vomit or stools. The epigastrium and appendix region were extremely tender. A gastric ulcer had been assumed, but the operation revealed that the appendix was drawn up by a kink in the mesentery, thus pulling on the region above, and inducing spasm of the pylorus. All disturbances ceased at once after appendicectomy. Gil compares with this case of appendicular dyspepsia the other abdominal affections liable to induce pain, emphasizing the various differential features of the pains. The appendix disturbances in his case were chronic from the start, as also the variation in the pain from day to day and from meal to meal. He advises to keep the patient under observation for a week and watch the type of the pains. He warns that with visceroptosis removal of the appendix will not banish all the symptoms. Chronic constipation with acute attacks of colic is also liable to prove misleading.

112. **Medical Ethics.**—Rojas discusses medical deontology in general terms, citing Faguet, Brouardel and others. He emphasizes in particular that as the principles of ethics should guide the physician's dealings with his colleagues and his clients, they should also guide his pen in his published works of a scientific nature.

116 Influence of the Soil on Evolution of Cancers. A. H. Roffo.—p. 567.

113. **Rupture of the Uterus.**—This 152 page instalment of González' monograph brings the total to 209 pages, with sixty-three illustrations. He reviews the history of the subject from Hippocrates to date of writing, the causes, remote and direct, and tabulates the indications for treatment, with the outcome in twenty-six cases. In only one of his spontaneous rupture cases was the uterus in such a state of degeneration that the rupture was inevitable. In all the others it could probably have been avoided with extra care. He declares that podalic version is dangerous even when done by an expert. The condition of the resistance of the uterine wall should be ascertained before attempting it, investigating the obstetric and gynecologic history, and examining the uterus, especially the cervix, with palpation and the speculum. The measures required to combat the hemorrhage are liable to aggravate the state of shock and invite peritonitis, the main complications. Iodoform gauze drainage alone proved successful in the four cases in which it was applied, but this is possible only when the primary hemorrhage is slight, and there is always danger of its starting up again. Tamponing with iodoform gauze by the genital route is difficult, insecure and dangerous, as he shows by some necropsies. It is liable to kink and interfere with the nutrition of various tissues. In two of his cases abscesses formed in the vicinity. At the same time, it gave him 71 per cent. of recoveries and one continuous series of nine successful cases. In those with unfavorable outcome, the aggravation of the prognosis was due to the further injury from hastening the extraction of the fetus. Only in exceptional cases is it necessary to apply the tampon through a laparotomy incision. In his total cases, 52.35 per cent. of the women recovered.

118. **Medical Significs.**—"Significs" and "semiantics" are recently coined terms to express workmanship in words, word-craft, and the deeper meaning of words. Van Rijnberk here commences a series of comments on medical word-craft.

119. **Behavior of Kidneys in Respect to Sugar.**—Hamburger recalls that sugar is always found in the blood but that it does not occur in normal urine. His research has apparently demonstrated that this difference is due to the fact that the membrane of the glomeruli possesses the property of holding back free glucose. This property of the membrane is influenced by the chemical composition of the fluid circulating through the glomeruli. In experiments on the frog, if the fluid passed through the glomeruli contained certain proportions of calcium, sodium and potassium, then the artificial "urine" after addition of 0.1 per cent. glucose contained 0.07 per cent. glucose, showing that 0.03 per cent. had been retained. Increasing the proportion of $NaHCO_3$ to 0.285 per cent., that is, to the proportion which normally occurs in the frog serum, then the glomeruli membrane holds back still more of the sugar, and the artificial "urine" is entirely free from sugar although the fluid passed through it contains 0.1 per cent. of glucose. The absence of sugar from normal urine is thus shown to be a phenomenon of permeability, and there is no reason for assuming any hypothetical binding of sugar with some colloidal substance—the *sucre virtuel* of Lépine. We have thus here a new form of physiologic permeability, in which the cells, under physiologic conditions, although readily permeable for salts, yet refuse to permit the passage of the equally crystalloid glucose. These researches throw light on the action of the usual therapeutic measures in diabetes and on phlorrhizin diabetes. Owing to the anatomy of the frog kidney, it was impossible to determine the share of the tubuli in this retention of sugar.

PROPHYLACTIC INOCULATION AGAINST PNEUMONIA

A BRIEF HISTORY AND THE PRESENT STATUS OF THE PROCEDURE [*]

E. A. FENNEL, M.D.
Lieutenant, M. C., U. S. Army
WASHINGTON, D. C.

We have just passed through—or rather, are passing through—a pandemic of disease, the gross and microscopic pathologic anatomy of which seems to be fairly constant in the hands of many observers and investigators, but concerning the etiology of which we continue to remain in much doubt. This pandemic had high incidence and mortality rates. In the great majority of cases, death was directly due to a bronchopneumonia. In those cases in which a bronchopneumonia developed, the death rate was so high as to be the cause of a panic, which made itself evident in the use of a wide variety of unjustified therapeutic and prophylactic measures.

It is too early as yet to draw any definite conclusions as to the bacterial etiology of the disease. Apparently well founded opinions have been advanced by experienced investigators setting forth diametrically opposed views. Since all the evidence is not yet, by any means, collected, conclusions would be premature and probably fallacious. Whether the cause has been the Pfeiffer bacillus, which has taken on extreme virulence, or whether a filtrable virus, or a streptococcus, *S. viridans* or *S. hemolyticus*, or a heretofore unidentified gram-positive coccus, it is too early to say. Whether the pneumococci of fixed or heterogeneous type are the true etiologic factors in this pandemic, which has cost the world so much in suffering, death and economic values, is not to be determined at this time.

It seems, however, to be agreed by competent observers that the disease itself was one of but transient duration, of from three to five days, in uncomplicated cases; bronchopneumonia was the most frequent of the complications or sequelae; and when this condition superimposed itself, pneumococci were found with regularity in the nose, mouth, pharynx and sputum of these patients. Since the mortality in the cases of bronchopneumonias was very high (during the height of the pandemic, 50 per cent. would have been a conservative estimate), ample opportunity for necropsy presented itself. Direct smears from lung tissue, and cultures from lung, bronchi, heart's blood, pleural, pericardial and peritoneal fluid, and from the spinal canal demonstrated the same regularity of the presence of pneumococci of the fixed and heterogeneous types. The presence or absence of other organisms does not bear on the subject in hand, though it might be said in passing that in a high proportion of cases, when careful technic was used, the pneumococci were found in pure culture. This fact has again stimulated research work on the pneumococcus, and has caused investigators and practitioners throughout the world to inquire, "Just what is the present status of prophylactic inoculation against pneumococcal infections?"

A bird's eye view of this subject presents, first, the great preponderance of the work on therapeutic measures in contradistinction to prophylactic measures, and, secondly, the apparent apathy of the profession as a whole concerning the prophylaxis of a disease that is of such vital and economic importance.

Theoretically, any disease of microbic origin, in which spontaneous recovery is at all possible, should yield to specific prophylactic measures. That recovery from pneumonia is spontaneously possible has long been known. During the years from 1881 to 1885, Pasteur[1] and Sternberg[2] produced a fatal septicemia in rabbits, and Frankel[3] and Weichselbaum[4] established the causal relationship of *Diplococcus pneumoniae* in lobar pneumonia. This was a great step in advance; but, though a large amount of work was done in the interim, some of which was highly confusing, it was not until Neufeld,[5] in 1900, determined the diagnostic value of the fact that pneumococci are soluble in bile, that the next step was taken. This knowledge enabled investigators to fix their attention on pneumococci, and rule out those bacterial forms so similar in morphology and cultural characteristics.

It had been noticed, however, that strains of pneumococci from different sources have different properties.

In 1909, Neufeld and Händel[6] definitely established the fact that some strains of disease-producing pneumococci had truly measurable antigenic properties. By injecting into animals a vaccine of a particular strain of pneumococci they were able to awake in that animal an immunity response. They also devised the method for measuring that immunity by conferring a passive immunity on a white mouse by injecting it with serum from the vaccinated animal, and then subjecting that mouse to an otherwise fatal dose of living pneumococci of the same strain. This fact, concerning that particular Neufeld strain of pneumococci (which later became the Group 1 of Dochez and Gillespie, or Group C of Lister), is the basis on which prophylactic inoculation against lobar pneumonia is built.

We were then on a footing where rapid strides could be made. A therapeutic serum was the direct outcome of the foregoing discovery, but interests us, in prophylaxis, only in passing. The predominant fact stood out that a certain strain of disease-producing pneumococci could stimulate, in an animal, a specific immunity response to that one particular strain. The word "group" should replace the word "strain," for it was found that the "Neufeld strain" was not limited to a race of pneumococci, but was found as Type I in widely separated cases.

GROUPS OF PNEUMOCOCCI

The logical outcome of this work was an investigation of the groups into which pneumococci might be divided, on a basis of their ability to stimulate *specific* antibody production.

In 1913, Dochez and Gillespie[7] in America, and coincidentally, though independently, Lister[8] in South Africa (where lobar pneumonia has been a problem of paramount importance), published their classification of the groups of pneumococci. Dochez and Gillespie used the protection tests of Neufeld, and specific agglutinations to evaluate their results; Lister used phagocytosis and specific agglutinations to arrive at his conclusions.

Dochez and Gillespie divided all pneumococci into four groups:

Group I (the Neufeld strain), distinct in its antibody stimulation.

Group II, culturally indistinguishable from Group I, but specifically distinct in its antibody stimulation.

Group III (*Pneumococcus mucosus*), identified by its morphology and its peculiar cultural characteristics. (Later its specific antibody stimulation was more definitely brought out.)

Group IV, all strains that would not fit into the preceding groups, irrespective of the fact that they stimulated an antibody specific for the strain, or stimulated no antibody. Into Group IV fit many of the saprophytic strains found in human mouths.

Lister was able to carry his classification somewhat farther than Dochez and Gillespie because of the greater multiplicity of groups prevalent in South Africa, and because of his added work in the heterogeneous group.

While the original classification of Dochez and Gillespie still stands, and is now quite familiar to the profession in America, Lister's classification has undergone additions until now he groups them as A, B, C, D, E, F, G, H, J, K, X and unclassified. Group A, numerically most important in South Africa, is unknown in America. Groups B, C and E are identical with Dochez and Gillespie's Groups II, I and III, respectively.

In general, Lister classified the pneumococci into a number of groups, ten in number, into which most pneumococci may be classified according to their group antigenic qualities, another group into which strains stimulating antibodes only against the specific strain, and an unclassifiable group into which are placed those few strains (3.3 per cent.) that give rise to no antibody production when injected into animals.

The relative importance, as measured by incidence and mortality of the pneumonias caused by these several types, varies from time to time and with localities. This fact does not seem to have been accorded the recognition it might better have received. While Groups A, B and C are of prime importance on the Rand, Group H, in a localized epidemic, suddenly sprang into prominence, and had to be specifically considered in prophylactic measures. The numerical preponderance of certain types of pneumococci in certain localities, during the pandemic, has called attention to this fact. The recent report of Friedlander and co-workers[9] at Camp Sherman called attention to this phase of the subject. They reported an incidence of about 80 per cent. of Type IV in their pneumonias. An analysis of these IV's and a consideration of them in the construction of a vaccine for use in that particular locality would have been logical. That such an analysis is feasible is indicated by the work of Olmstead,[10] and should be carried farther.

Particular attention is directed to Lister's classification, for two reasons; first, because it emphasizes the need of further investigation and classification within our American Group IV, and, second, because it demonstrates the multiplicity of factors to be considered in specific prophylaxis against lobar pneumonia.

WORK OF WRIGHT AND OF LISTER

It is unfortunate that so great an authority as Sir A. E. Wright, and his co-workers, should have undertaken an extended experiment in the inoculation of a large number of mine workers, in South Africa, at a time that was so unripe.

Between the time that Neufeld established the antigenic value of pneumococci, and the time that Dochez and Gillespie, and Lister established the varieties and specificity of the groups of pneumococci (namely, in 1911 and 1912), Wright and his co-workers[11] vaccinated a large number of native South Africans.

In the preparation of their saline vaccine they necessarily did not take into consideration the predominant types against which this measure was aimed. Further, in those cases of pneumonia that developed after vaccination, no cognizance could be taken of the groups to which the etiologic organisms belonged. Their results were evaluated by estimation of opsonic indexes—a method that has fallen into much popular disfavor, and by statistics, employing groups of "controls" for comparison, a method that brought about much argument concerning the method of selection.

In a historical study of pneumococcal vaccination, Wright's work must, of course, be considered; in a critical study of the subject it would be better to consider his work only in passing, lest the inopportune time at which it was undertaken and the paucity of our knowledge at that time befog any conclusions that might be drawn.

Lister's work, however, was built on an entirely different foundation. He was well armed with the knowledge of the types that predominated in his field of endeavor, and could take the selection of those strains into consideration in constructing his vaccine. The many technical difficulties of producing large numbers of pneumococci in a concentrated form were somewhat reduced by his apt adaptation of a cream separator for centrifugalizing broth cultures. Above all, his knowledge of the types of pneumococci permitted him to evaluate correctly the significance of those cases of pneumonia that did follow his inoculations.

[10] Olmstead, M.: Jour. Immunol., 1917, **2**, 425.

[11] Wright, A. E., et al.: Lancet, London, 1914, **1**, 1, 87.

Forearmed in such a fashion, he was enabled to construct a vaccine, limited to those types most potent in the production of lobar pneumonia on the Rand, namely, Groups A, B and C. He determined by extended animal experimentation that these vaccines intravenously, and subsequently subcutaneously, gave rise to demonstrable antibodies. A limited number of intravenous inoculations in human beings was next tried, but the apparent impracticability of such a method caused it to be discarded, though antibody production was good. A limited number of subcutaneous vaccinations in man then assured him that this method was not only productive of results, but quite applicable to large groups of native laborers. Pneumococcus vaccines are noticeably less toxic than many others we are more familiar with, and, coupled with the fact that the South African native is slightly disturbed by bodily discomfort, Lister was able to inoculate a large number of these natives subcutaneously, each with three doses of a saline vaccine, of high bacterial content, at seven day intervals, without undue disturbance.

He was able to keep a large proportion of these subjects under observation for a period of nine months or longer, and his results are startling. It would be presumptuous to try to sum up such a monumental work in a few words. To those interested in this subject Lister's most recent publication[12] is earnestly commended.

His Crown Mine experiment is of particular interest. During a nine months' period, approximately 11,000 natives were inoculated with a vaccine that included Groups A, B and C. During that time, in these 11,000 vaccinated natives, eighty-two cases of lobar pneumonia resulted, but not a single case was caused by a pneumococcus of either Group A, B or C. Had the prevalence of Groups A, B and C remained constant with the other types, lobar pneumonia cases due to Groups A, B and C to the number of 120 would have developed.

There seems to be no doubt, then, judging from Lister's work, that, if the prevalent types of pneumococci be considered in the elaboration of a vaccine, sufficiently rich to be effective, that vaccine should be almost 100 per cent. efficient *for the specific types.* (Lister rather inclines to large doses and considers a total of 6,000 million cocci of each group against which protection is sought as the minimum.) Three inoculations at intervals of seven days are necessary, and the local and systemic reactions following the vaccinations are far outweighed by the beneficial results.

As a matter of fact, these published results are so good that one is apt to recall the proverb, "Timeo Danaos et dona ferentes."

WORK OF CECIL AND AUSTIN

Their true worth is practically vouched for, and the results amply confirmed by the recent work of Cecil and Austin.[13] They prepared a saline pneumococcal vaccine of Types I, II and III, much after the fashion of Lister. This vaccine, under the direction of Colonel Russell, was used at Camp Upton, to vaccinate 12,519 men. Animal experiments and limited ones in human beings had served to demonstrate that this vaccine had antigenic effect, measurable by agglutinins, and the protection the serum of vaccinated individuals conferred on mice. The vaccination of troops began Feb. 4, 1918, and these troops passed from observation about April 15, 1918, making the period of study about ten weeks. The three inoculations were given at seven day intervals, except in those cases that showed a marked reaction after the first or second dose, in which cases it was discontinued. For the sake of simplicity, their results might be tabulated as in Table 1. Any more critical analysis of these figures or cases serves only to accentuate the apparent efficacy of the vaccine.

It will be noticed that a Type I, II and III vaccine seemed to prevent practically all cases of pneumonia due to those types, and caused an apparent protection, not only against Type IV, which might have been suggestive of cross protection, but also against *Streptococcus hemolyticus* and *S. viridans.* The authors offer no explanation of this fact. It is possible that so much foreign protein injected into the human being has caused him to mobilize his ferments and leukocytes, as demonstrated by Jobling and Petersen,[14] to the increase of a natural resistance. It is further possible that this change in ferment-antiferment balance has conferred on the individual, besides the specific immunity, an additional resistance against a large number of other bacterial invaders.

TABLE 1.—INCIDENCE OF PNEUMONIA AMONG VACCINATED AND UNVACCINATED TROOPS: RESULTS OF CECIL AND AUSTIN *

Pneumonia Cases of Types	Vaccinated, 40%	Unvaccinated, 60%
Type I	1†	10
Type II	0	9
Type III	0	7
Type IV	0‡	33
[illegible]	6	72
[illegible]	1	34
[illegible]	0	7
Total	17	172

* Average strength of command, 3,200.
† Developed twenty-four hours after first injection.
‡ In three cases only one injection was given.

There is little room, therefore, to doubt that saline pneumococcal vaccination is highly efficient for the specific types contained in the vaccine. Within that limitation, it bids fair to rival typhoid vaccination, about which there has for some time been no doubt.

SALINE VACCINE AND LIPOVACCINE

The saline pneumococcus vaccine has the advantage of being an efficient prophylactic. It has, however, certain distinct disadvantages. Production of such a vaccine on a large scale has always been a difficult, trying and somewhat expensive procedure. The time limit on such a vaccine, owing to comparatively rapid autolysis, must be short, and this would serve to increase its price, an important consideration when widespread measures are contemplated. It must be given, so that a sufficiently large dose to be effective is administered, in at least three, preferably more doses, at seven day intervals. The difficulties that this offers to the general use of a prophylactic measure are most obvious to one who has worked in the public health field, though the rural practitioner, advocating the saline typhoid vaccine, has had ample opportunity to feel this disadvantage.

---

[12] Lister, F. S.: Publications VIII and X, South African Inst. for Medical Research, 1916 and 1917.

[13] Cecil and Austin: Jour. Exper. Med., 1918, **28**, 19.

[14] Jobling, J. W., and Petersen, William: The Nonspecific Factors in the Treatment of Disease, THE JOURNAL A. M. A., June 3, 1916, p. 1753.

While pneumococcal vaccines in general are not so toxic as typhoid vaccines, the fact that quite frequently a saline injection is followed by a sharp reaction militates strongly against its general use.

Almost all of the foregoing disadvantages are overcome by the use of a pneumococcus lipovaccine. A lipovaccine is one in which the bacteria are suspended, not in saline solution, but in an oil or lipoid vehicle. By this means autolysis is greatly prevented, absorption is slow, and massive doses can be given at one injection, thereby reducing the number of inoculations to one. Not only does the oil retard absorption, but there is good cause to believe that the lipoid substances serve directly to reduce the toxicity. Such a vaccine was first elaborated by Le Moignic and Pinoy[15] for triple typhoid vaccine, and has been adapted by the Army Medical School[16] to a wide variety of vaccines.

As early as December, 1917, a pneumococcus lipovaccine had been elaborated at the Army Medical School.[17] Colonel "W" received the first dose, and, along with Capt. "C," the other subject, responded by the production of agglutinins. The reactions to the vaccine were so mild that Colonel "W" repeated the vaccination on the two succeeding days, the third dose being followed by a slight chill. In each of these doses he received the total of three saline doses.

The work on the pneumococcus lipovaccine was somewhat delayed, owing to the fact that a triple lipovaccine had to be perfected, one that subsequently came into use in the Army to the exclusion of the saline vaccine.

Animal experiments with the pneumococcus lipovaccine of Types I and II seemed to show some protection as a result. A direct systematic comparison was then made between two types of saline vaccines, one of the latter being the one in use, at that time, at Camp Upton, which was to show, at a later date, such excellent results.

In these tests, one of the lipovaccines, which could be given in one dose and which caused only a slight reaction, was found to be so far superior to the other three types that it was made on a slightly larger scale and altered by the addition of Type III and used, to the extent of about 25,000 doses, in the military camps. This was a vaccine of high bacterial content, but the reactions following were very mild. The reports, following its use, and the coincidental pandemic, with the attendant pneumonias, confirmed the wisdom of adopting this vaccine as a general but voluntary measure in the Army, a step that had been taken some time previously.

It is to be emphasized that this was not a vaccine, developed over night, as a prophylactic against influenza; it was a vaccine aimed at pneumococcal infections, developed systematically at a time considerably antedating the present pandemic.

This lipovaccine seems to overcome all the difficulties associated with a saline vaccine except the expense and ease of production. It is somewhat more laborious to produce such a vaccine, and the use of oil and the mechanical equipment necessary make it more expensive.

UNITED STATES ARMY VACCINE

The particular type of vaccine in use in the U. S. Army is made as follows:

The three types of pneumococci are grown separately in a beef infusion broth, incubated not more than eighteen hours, and the organisms recovered by the use of a continuous feed type of centrifuge, a perfection of the type used by Lister. On this centrifuge, spinning at a rate of 40,000 revolutions a minute, depends the effective removal of the pneumococci. The organisms are thus secured in the form of a heavy mass of about the consistency of library paste. This mass, under glass hoods and under aseptic conditions, is then smeared in thin layers over the bottoms of Petri dishes, which are next covered with an earthenware top. In these Petri dishes the bacterial material is then brought to complete desiccation in a 53 C. incubator, liberally supplied with unslaked lime. The average water loss is about 80 per cent. This drying process is a matter of only a few hours, and little morphologic change in the organisms takes place, since they may again readily be suspended in saline and present themselves as gram-positive cocci of sharp, clear staining characteristics.

This material, now dry, readily flakes off from the glass, and is pooled, again under the hood, into one container. It is then measured out by weight to establish the dosage. The decided advantage of the use of weighed quantities of dry bacterial material to determine the dosage is, after a moment's thought, quite apparent. Many of the fallacies attending dose determinations in saline vaccines are obviated by the use of weights. It has been found that a unit of dry bacterial mass represents a fluctuating number of bacteria, depending on the virulence of the organisms, cultural environment and time of incubation.

The Army vaccine contains dry material equal, in round numbers, to 10,000 million of each type. Those figures are, of course, only relative, and it must be insisted on that dosage by weight is constant, while dosage by count is notoriously fluctuating and inaccurate.

After the dry material has been carefully weighed under sterile conditions, and calculated so that each cubic centimeter of the finished vaccine will contain 0.83 mg. of each type, the bacterial flakes are placed in a sterile grinding jar, along with sterile steel ball bearings, the jar is placed on a mill, and during the course of twenty-four hours the bacterial mass is ground to a fine, amorphous powder. At the end of that time a mixture of anhydrous lanolin and cottonseed oil, in a proportion of 1:2, is added, so that the completed vaccine shall contain 2 per cent. of lanolin. The mass is then thoroughly emulsified by grinding twelve hours, at the end of which time cottonseed oil is added to make the final dilution, along with 0.5 per cent. chlorbutanol as a preservative. The grinding is then continued twelve hours. The oil and the lanolin-oil mixture has been sterilized by autoclaving at 15 pounds for thirty minutes.

This completed vaccine is then subjected to rigorous cultural tests, and is finally injected into animals, to insure sterility. It is then ampuled and distributed for use. Its administration is a simple matter if a needle of 23 gage or any larger bore is used. While sedimentation does occur, cottonseed oil is only so slightly viscid that an even suspension is easily attained by slight shaking.

Several commercial firms are now actively producing, or preparing to produce, a vaccine modeled on the foregoing plan. Supervisional tests, by the government, of sterility will be a relatively simple matter; tests to evaluate the antigenic efficiency of the vaccine will be attended by greater difficulties. These, however, no doubt will be met.

It might be interesting to mention that the Army Medical School has manufactured and sent out for use during October and November, 1918, more than two million doses of this vaccine. The magnitude of this undertaking is better understood when one recalls that Lister, the master himself, said that the manufacure of 40,000 doses for the British government on short notice was out of the question.

RESULTS OF VACCINATION

Much had been hoped for when the tabulated results of this widespread vaccination would have been available. The abrupt cessation of the war, and the rapid demobilization that must follow, will withdraw from observation this large number of vaccinated men. Much valuable information, however, should come to light in the due course of time. Laboratory methods that have stood the test of time were used to test the value of the vaccine, and the results have been found particularly gratifying.

Such a vaccine as is issued by the Army has been injected into human beings, and tests have been made. Ten weeks after injection, 0.2 c.c. of the serum of these subjects almost regularly protects a mouse against 1,000 times a dose of living pneumococci that would otherwise be fatal.

Preliminary clinical reports seem to be highly satisfactory. Some of the unexpected results, such as made their appearance at Camp Upton, seem to be following the use of the lipovaccine. While a specific immunity against the three types of pneumococci in the vaccine was all that was hoped for, a certain freedom from respiratory diseases in general seems to have followed its use. Absence of bronchial symptoms in influenza, after vaccination, was noticeable. While the information at hand is fragmentary, and not to be seriously considered, it may be a straw to show the direction of the wind. For example, fourteen women war workers living in one house were exposed to about the same conditions. Twelve were vaccinated at the beginning of the pandemic in Washington, and remained well and on duty throughout that pandemic. The two unvaccinated ones both contracted influenza. Of a number of men on duty in a Washington fire department, two refused the vaccine; these two alone of that company contracted influenza. Such apparent nonspecific protection seems somewhat visionary until one recalls the fact that even normal brain substance increases resistance against rabies, a disease of specific origin. Vaughan[18] noted this resistance following the injection of his protein split products, Zinsser and Dwyer[19] have discussed it, Joblin and Petersen[20] observed it after serotoxin injections, and Teague and McWilliams[21] noted it after typhoid vaccine shock.

The studies of Jobling and Petersen[20] and of Scully,[22] Culver[23] and Petersen[24] endeavor to explain the modus operandi of this increased resistance.

Studies have been made at the Army Medical School to note the relationship between triple vaccination and streptococcus infection. Medlar[25] shows that triple typhoid vaccination does not predispose to streptococcus infection and might seem to increase the resistance. Smith's[26] study of cytologic changes after the same vaccination might explain some of the nonspecific protection noted.

It is true that to demonstrate increased protection after the injection of foreign proteins it is customary to use large doses intravenously; it is possible that such small doses as 25 mg. (the total content of the Army vaccine) might serve to establish a relative immunity.

In connection with the nonspecific value of a vaccine, and in relation to the particular vaccine issued by the Army, Table 2 might be of interest. Mice, vaccinated with a saline and a lipopneumococcus vaccine, along with control mice, were subsequently injected with low virulence *Streptococcus hemolyticus* cultures. It would seem that the lipovaccines render the mouse more susceptible to large doses of streptococci, but render it more resistant to smaller doses. Since the latter case more closely simulates the natural mode of infection, the experiment, limited though the series is, may help to explain some of the so-called "cross protection" results. The more gradual absorption of the lipovaccine might account for the difference between it and the saline vaccine.

TABLE 2.—RESULTS IN A SERIES OF MICE INOCULATED WITH PNEUMOCOCCUS VACCINE, TESTED TO DETERMINE THEIR RESISTANCE TO HEMOLYTIC STREPTOCOCCUS TWO MONTHS AFTER VACCINATION; SEPT. 15, 1918

* Twenty-four hour culture, low virulence Streptococcus hemolyticus.

"MUSHROOM" VACCINES VERSUS PNEUMOCOCCUS LIPOVACCINE

Consideration of the many "mushroom" vaccines that sprang up over night during the pandemic, and which, besides a multiplicity of other organisms, were made to contain a questionable number of pneumococci, is purposely omitted. That they may have served some purpose in a specific immunity is possible, but hardly probable. In these justly called "shotgun vaccines" the content of the individual groups must necessarily have been so small as to be

unable to lift the patient over the threshold of appreciable immunity.

That the vaccines may have had some nonspecific value, comparable with that of the vaccine used at Camp Upton, cannot be denied. However, the burden of the proof rests with the originators of these vaccines, and their value should be weighed on the merits of the vaccines alone. Such a judicial decision is, at this time, of prime importance. We have not passed through the pandemic of influenza with its sequelae; we are passing through it. If the history of the last great pandemic[27] is to be of any value, it should teach us to be on the alert for the recrudescences that must occur throughout this year, as well as in the following three or four years.

It is a better policy to use one instrument, if one is thoroughly familiar with it, limited though its uses may be, than to use a wide variety of unfamiliar, complicated ones.

We feel that pneumococcus lipovaccine is such an instrument. We feel that we have definite assurance that it will prevent infection by Types I, II and III. Epidemiologic studies of localized epidemics, that would justify the addition of purely local types to the vaccine, are to be encouraged. The lipovaccine is such that much additional pneumococcus material may be added, without increasing its toxicity.

The advantages of such a vaccine—its lack of toxicity, its simplicity of administration, and the high degree of immunity conferred—should, during the remainder of this winter, and during the next several years, when we shall most probably be called on to combat recrudescences of the pandemic, with its attendant pneumonia, be a useful weapon. Not only should it have its place in the Army, but also it should be seriously considered by those physicians in charge of industrial ventures, such as mines, steel mills, ship yards and the like. Such a vaccine must come from a source that is unquestionable and one that is capable of massive production. Such a demand from civilian sources might be satisfied by the Army, if the necessary arrangements could be made, until the supply would be forthcoming from normal channels.

CONCLUSIONS

1. Prophylactic pneumococcus vaccination is successful over an extended period of time for those groups represented in the vaccine.
2. A pneumococcus lipovaccine, of slight toxicity, to be given at one injection, has been elaborated, and has had widespread use. Early reports indicate its usefulness.

Maternal Nursing and the Sculptor's Model.—Rickets, a disease of nutrition, still too common with us, is but rarely seen in Italy, where it is the universal custom for mothers to suckle their infants, and whence accordingly come those shapely human forms that are chosen by our sculptors and artists for their models. Mothers unquestionably suffer in health and happiness from the suppression of a function which should form a pleasurable and wholesome episode in their existence, and it has been suggested that the prematurely aged and withered appearance of the married women in the manufacturing districts is in some degree attributable to the check imposed on the lacteal process in them by their employment, when that process has been once fully established.—Sir James Crichton-Browne, *Journal of State Medicine*, May, 1918.

AN EXPERIMENTAL STUDY OF THE SURGERY OF LARGE ARTERIES: ANEURYSM

THE PLACING OF MUSCULOFASCIAL INSERTS WITHIN AND THEIR USE IN PATCHING ARTERIES

FREDERICK C. HERRICK, M.D. (Cleveland)
Major, M. R. C., U. S. Army
CAMP CRANE, ALLENTOWN, PA.

It is well known that exposure of blood to extravascular tissue favors clotting. This fact is often used, especially in surgery of the brain, for the control of small bleeding points. However, the ability of normally circulating blood within the arteries to withstand the coagulum-producing influence of foreign tissue has not, to my knowledge, been given special study.

The object of this research was, therefore, to investigate the occurrence of clotting about an intravascularly placed piece of foreign tissue (muscle and fascia). The first conception was that such a condition would rapidly produce clotting, and if the tissue placed within the vessel were of appreciable size, thrombosis would likely occur.

The results of this research, however, have not upheld this first conception, and it has been found that relatively large musculofascial inserts may be placed within arteries (as the aorta of a dog) without producing serious obstruction to the blood current.

The breadth of application of this fact to the surgery of aneurysm or the repair of large blood vessels is evident:

1. The wiring of large aneurysms is inaccurate, and even when, by chance and experience, the wire coils properly, the results have been encouraging in only a few cases. Both the wiring operation and Halsted's rings placed proximally to the aneurysm are foreign bodies in the tissues, and comprise the disadvantages of such measures. The use of musculofascial inserts at the opening of aneurysmal sacs for closing the openings, or so placed as to limit the size of a sac or fusiform aneurysm, is a possibility and led to this research. Furthermore, instead of measures such as Halsted's rings about a large vessel proximal to the aneurysm, it was found that tissue inserts may be used to control the volume of blood passing through the vessel and hence to the aneurysm. The great variety of aneurysms was well appreciated, and the fact was well apparent that much work would be necessary for the application of the method to the different forms of sacs.
2. In the repair of injured vessels, direct intimal apposition has been thought necessary. In the light of this research a patch of fascia, muscle or both may be placed over an injured artery, covering a defect without producing thrombosis of the vessel.
3. In the replacement of segments of vessels, pieces of other vessels have always been used. In dogs, by maintaining a certain part of the circumference of a vessel the balance may be built up with fascia and functionates perfectly, and thus an intimal lining is formed. Its source is open to question and is a problem for further research.
4. In some cases a definite plug of muscle and fascia may be placed against a circumscribed opening in an artery.

The subjoined experimental protocols form a preliminary report:

PROTOCOLS OF EXPERIMENTS

The first series was begun, Nov. 10, 1917, at the Cleveland City Hospital.

Experiment 1.—A small fox terrier was anesthetized with ether, a midline abdominal incision was made, the intestine was pushed to the right, and the aorta exposed. A No. 2 chromic ligature was passed around it in two places, 1 inch apart between the origin of the renal arteries and the bifurcation, and its pulsations were controlled by traction. A fine dulox skin needle, with silk attached, was passed through the aorta, including the anterior third as a sector. Under traction on this suture, a fine pointed knife was entered beside it, making a slit 1 mm. long in the aorta. A strip of external oblique fascia attached to the thread was drawn through the aorta by means of these two openings. After the passage of the fascia, although the slits had been made, there was absolutely no bleeding. The fascia projected 0.5 cm. on each side. The abdomen was closed in three layers. The dog recovered rapidly from the anesthesia. There was a well marked femoral pulse of 200.

Necropsy.—Jan. 15, 1918, sixty-five days after operation, the dog was killed. When the aorta was slit open through the point of operation, there was no clot present. A piece of intima-colored tissue projected into the lumen 3 by 3 mm. thick.

Experiment 2.—A medium sized mongrel was anesthetized with ether, the aorta was exposed, and a piece of fascia and muscle 3 mm. wide was passed through it. A single suture was placed on each side of the vessel wall at the proximal end of the opening to control hemorrhage around the transplant. Closure was made in three layers. The femoral pulse after operation was 160.

Necropsy.—Feb. 10, 1918, sixty days after operation, when the aorta was slit open through the site of the insert, the same condition was found as in Experiment 1.

Experiment 3.—A medium sized mongrel was anesthetized with ether and the aorta exposed. The pulse was controlled by traction sutures. A fine bladed knife was passed through the aorta and a piece of tissue composed of external oblique fascia, muscle and peritoneum was passed through the aorta. The piece was three-fourths the size of the aorta. However, when passed through on tension it was probably not more than half the size of the aorta. Its ends were held together in front of the aorta by one stitch. It was noticed that very slight traction on this tissue in any direction except transversely readily produced hemorrhage around it, but immediately on ceasing to pull and allowing the tissue to contract, the hole in the aorta was plugged and bleeding stopped. Closure was made.

Necropsy.—Feb. 12, 1918, forty days after the operation, the condition was found to be the same as in the two preceding experiments. The amount of tissue present within the lumen was equal to one-fourth the lumen. No clot was present.

The foregoing series was interrupted by my receiving orders for military service. An opportunity did not present itself for continuance of the work until a change of station took me to Fort Des Moines Base Hospital as chief of the surgical service. During my six weeks at this post, the following experiments were completed:

Experiment 4.—July 30, 1918, a small fox terrier was anesthetized with ether, the aorta was exposed, and a piece of fascia and muscle two-thirds the size of the aorta was passed through it. Three stitches were necessary on the left side proximally to the insert, distally and at a midpoint. A good pulse was present with a thrill over and distal to the insert. July 31, a good femoral pulse was present. The dog was sick. August 1, it died.

Necropsy.—Two days after operation the cause of death was found to be general peritonitis, through some fault in technic. The aorta was slit open over the insert. A clot was present which might be called an icicle clot, since it suggested such a formation. Its base started from and surrounded the insert, from which it tapered slightly to its blunt tip 6 mm. distally. Extending proximally was the same formation 7 mm. long. A pair of lumbar arteries 1 mm. in diameter opposite the clot was not thrombosed.

Experiment 5.—July 27, 1918, a large brindled bull was anesthetized with ether, the aorta was exposed, and a piece of muscle and fascia two-thirds the size of the aorta passed through its center. Bleeding occurred from the corners of the incision, but was entirely controlled by four stitches. A good aortic pulse with a thrill was present distal to the insert. July 28, the dog was in good condition; there was no weakness of the legs, and a good femoral pulse was present. July 31, a good femoral pulse was present. Under ether anesthesia the abdomen was opened and a good aortic pulse distal to and over the insert was verified.

This observation was made because it was thought possible that the femoral pulse might result from a collateral circulation more easily established in dogs than in man. The pulse, however, was present over and immediately distal to the insert. There was no collateral circulation present. In later experiments, when a thrombosis was intentionally caused, the dogs showed weakness of the hind legs for a variable time after operation.

Necropsy.—Four days after operation, the aorta was slit open through the site of the insert. An icicle-shaped clot was found extending 9 mm. from the insert distally. There was some irregular clot proximal to the insert, attached to it. A pair of small lumbar vessels branching opposite the middle of the distal clot was thrombosed.

Experiment 6.—Aug. 6, 1918, a large white mongrel was anesthetized with ether, the right carotid was exposed, and two pieces of tissue taken from the neck were passed through it transversely 2 cm. apart. The proximal insert consisted of muscle and cervical fascia 2 mm. in thickness. The distal insert consisted of cervical fascia with some fat attached, 2 mm. in diameter.

August 11, five days after the operation, the carotid was exposed under ether anesthesia; a full pulse was present over and distal to the inserts. The carotid was excised and slit open. The inserts were both present, 2 mm. wide, projecting into the lumen, reducing it by approximately one half. No clot was present.

Experiment 7.—Aug. 5, 1918, a female (the same animal as in Experiment 8) was anesthetized with ether, the aorta was exposed, and a piece of muscle fascia was passed through a slit 4 mm. long. No sutures were necessary. A good pulse was present below the insert with a marked thrill. From August 6 to 10 the animal was in good condition with a good femoral pulse.

August 11, six days after the operation, under ether the abdomen was opened, and a good pulse over and distal to the insert was verified. When the aorta was slit open, no clot was found. The large insert was present, of the same color as the intima. When it was placed through the aorta at operation, the sides of the vessel had apparently been drawn together and held there, so that only a small segment of insert presented itself to the blood stream, and the lumen of the vessel had been reduced by one third. Thus it is possible to reduce the caliber of an artery markedly by this method. If done proximally to an aneurysm it would greatly diminish the volume of blood passing into the sac as well as the speed of its passage through the sac. This would appear to be a good method for bringing about such a condition of circulation. Whether such a procedure is preferable to the direct attack on an aneurysm by transplants should be later worked out, for the same technic might be used in reducing the size of the sac or its opening. And here seems to be one of the lessons learned by this study: By passing musculofascial transplants, transversely, obliquely and longitudinally, one or all, through an aneurysmal sac, the latter's capacity can be lessened. This, together with the clot-producing power of such tissue when exposed to blood under other conditions favoring clotting, can be used to thrombose entirely an aneurysmal sac. From observations in some of these experiments it seems possible so to place these inserts in a sac that a proper current would be left for vessels branching from it.

Experiment 8.—Aug. 2, 1918, a small terrier was anesthetized with ether, the aorta was exposed, and a strip of rectus muscle and fascia one-fourth the size of the aorta was passed through the midpoint transversely. No stitches were necessary. A good pulse with a thrill was present over and below the insert. Closure was done. August 3 to 10 there was a good femoral pulse.

August 11, nine days after operation, under ether, the abdomen was opened and a good pulse over and distal to the insert was verified. When the aorta was slit open, no clot was found. The insert measured 6 by 2 by 2 mm., and was the same color and appearance as the intima. It reduced the lumen of the aorta by fully two-thirds its volume.

Experiment 9.—July 17, 1918, a large female mongrel was anesthetized with ether, the aorta was exposed, a slit 0.5 cm. long was made longitudinally through both walls, and a piece of external rectus sheath and muscle equal to the diameter of the aorta was passed through. There was no bleeding around the insert. There was a pulse, distal to the insert, with a thrill. Closure was done. There was a good femoral pulse. July 18, the dog was active; a full femoral pulse was present. The condition continued the same till July 31 (fourteen days after operation). Under ether anesthesia the abdomen was opened. A good pulse was felt in the aorta immediately distal to the insert and at the site of the insert, where the vessel was felt thickened and a moderate mass of adhesions was present.

Necropsy.—The aorta was slit longitudinally through the insert, and the insert was accidentally cut. The insert was 6 mm. in diameter, the aorta, 1 cm. in diameter. No clot whatever was present.

Experiment 10.—July 16, 1918, a small fox terrier was anesthetized with ether, the aorta was exposed, the circulation was controlled as above, a slit 1 cm. long was made through both walls laterally, and a piece of anterior rectus muscle and fascia equal to the size of the aorta was passed through the aorta. Four stitches at the ends of the slits were necessary to control the bleeding. A faint pulse was felt distal to the insert. Closure was made. A very faint femoral pulse was present. From July 16 to July 24, no femoral pulse could be felt. July 25, a faint femoral pulse reappeared. July 25 to August 8, the femoral pulse increased to normal volume. August 8, the animal strangled herself on her tie rope; she had been very well and active.

Necropsy.—Twenty-three days after operation, a section of the aorta, including the iliacs, was excised. The aorta was slit open; no clot was present. The insert was found; it measured 3 by 3 mm.; it was firm, was closely adherent to the anterior wall of the aorta and had a gray, glistening appearance indistinguishable from the intima. It reduced the aortic lumen by two thirds.

Experiment 11.—July 7, 1918, the same animal as in experiment 4 was anesthetized with ether, the right carotid was exposed, and with a fine knife the anterior half of the vessel wall was excised for 1.5 cm. A piece of external rectus muscle and fascia 3 mm. thick was removed and sutured as a patch over the carotid defect with the muscle surface projecting into the lumen.

July 28, the wound was clean. August 11, twenty-four days after operation, under ether anesthesia, the carotid was reexposed and found to have a full pulse throughout its extent. A small sacculated aneurysm was present, with an opening 4 by 4 mm., a depth of 2 mm., and its cavity 5 mm. at the widest point, occupying the position of the musculofascial patch. The carotid was removed and slit open. There was no clot whatever present. The patch had held firmly but had bulged out to a depth of 2 mm. It contained no clot. The inference from this case is that such a patch, if applied in man, would give rise to an aneurysm. The fate of transplanted tissue is well known, and the resulting scar tissue in this case must be very firm and strong in order to withstand arterial pressure. It looks as though intra-arterial or intra-aneurysmal transplants would be of greater value in the treatment of aneurysm.

A complete report on the foregoing work, with photographs of the specimens and histologic examinations of the tissues will be made later. The exigencies of active military service render such studies difficult. The following conclusions seem fair, and I regret that lack of time will not permit a discussion of the many points of value that have been observed.

SUMMARY AND CONCLUSIONS

1. Strips of rectus fascia with muscle attached of varying size up to three-fourths that of the aorta of dogs may be placed through a dog's aorta or carotid without causing permanent clot or thrombosis. In certain cases no clot at all is formed.

2. In over half the experiments, the contraction of the aortic walls about the inserts and of the inserts against the slits in the aorta entirely controlled hemorrhage. In the remaining cases, from one to four simple sutures controlled bleeding from the corners.

3. These inserts diminished the lumens of the aortas to approximately one-third to three-fourths their former volume.

4. Such inserts may be used to diminish the volume of a large artery, to diminish the orifice of a sacculated aneurysm, to favor thrombosis of the aneurysmal sac by being placed through it, or to limit the size of a fusiform aneurysm by being placed so as to exclude certain sectors from the current.

5. In no cases have symptoms of embolism been noted. The only pathologic observations to exclude such an occurrence were: (a) In two cases examined at necropsy within six days, no clot was formed at all. (b) In four cases examined at necropsy later than six days, no clot was present. (c) In all cases but one, when a clot was formed it took a uniform, blunt tipped icicle shape, was quite firm, and would not easily break off.

6. A patch of fascia or muscle may be sutured to an arterial defect with perfect functional results.

7. The sac of an aneurysm or the vessel proximal to it may be lessened in volume by such inserts.

8. An arterial patch of muscle and fascia in a dog is consistent with perfect function of the artery.

CHRONIC ARSENIC POISONING ON A FARM

REPORT OF A CASE

SAMUEL AYRES, Jr., A.B.
BOSTON

History.—A woman, aged 22, seen by Dr. Samuel Ayres of Kansas City, Mo., to whom she was referred by her local physician in Summers, Ark., complained of sore mouth, indigestion, weakness and general tenderness. She had been married two and one-half years; she had had no children nor miscarriages. She had had mumps, measles, whooping cough and scarlet fever during childhood; there had been no operations. Previous to her present illness she had been entirely well. She had had a well-balanced diet. She lived on a farm and had no other occupation aside from her household duties. Prior to five years before she had been employed in a fruit drying factory for three years, where she said that she was exposed to sulphur vapor. She also spent a great deal of time spraying fruit orchards, and said that she ate fruit which had recently been sprayed. The spray, she thought, contained arsenic. This immediately preceded her present illness, which began five years before. On questioning, she was quite sure that she had *not* been exposed to arsenic during the past five years. She had moved away from the fruit orchard. There was no family history of tuberculosis. A year and a half before, the patient's brother, who was then 22 years old, was operated on for appendicitis, following several intermittent attacks of severe abdominal cramps. The operation gave no relief, and the attacks of cramps had persisted up to the present time. The brother had a papular skin eruption on his face and back. A sister also had had trouble with her skin for some months.

Present Illness.—Skin: Five years before, in May, a papular eruption appeared on the forehead and chin, which spread to the body, chest, back and shoulders, scalp and face. This was diagnosed by a local physician as eczema, and treated by local applications which, instead of giving relief, only made matters worse. The eruption consisted of papules and pustules which bled when opened. Some were as large as the little finger nail, and often ruptured spontaneously, bleeding profusely and soiling the clothing. The condition of the skin had been variable, sometimes better, sometimes worse. For the past year or more there had been a more permanent brownish pigmentation of the face. Heat or wind caused the face to burn and sting.

Sensation: About a year later, or four years before being seen, a burning sensation of the mouth, tongue and lips was noticed. The patient said that her tongue was red, and that the lips were blistered and peeled. The burning sensation later spread to the chest and epigastrium, and at times a sense of burning and tenderness was general over the entire body so that merely touching her caused pain. The patient said that sometimes her hands felt as if they were three times their normal size. They often felt numb, or tingling, and she had frequently cut or burned herself without feeling any pain. About two years before, her eyes began to cause trouble. After looking at objects for even a short time, her eyes would become tired and the vision blurred. At times the patient had lost her sense of smell and taste. For the past three weeks water had tasted bitter.

Digestive Tract: The appetite had been variable; there was no vomiting; the patient was not often nauseated. During the past two years there had been discomfort after eating. From fifteen to thirty minutes after a meal, a heavy feeling was noticed in the stomach, which frequently caused the heart to beat rapidly. Often there was a bitter taste in the mouth soon after eating. Because of these symptoms, and on account of the sore mouth, the patient had eaten but little. For periods of a week or two at a time, the patient had been troubled with an excessive flow of saliva. The bowels were constipated, moving once in two or three days. There had never been any diarrhea. The rectum was sore and burned.

Cardiovascular: At times the heart beat so rapidly that it was quite uncomfortable. This was brought on usually by eating or by overexertion. There was no dyspnea.

General Condition: The patient felt weak. She had lost both strength and weight. Her best weight three years before was 123 pounds; the present weight, three weeks before, 99½ pounds.

Genito-Urinary: Menstruation had been irregular during the past three years, with considerably more pain. Often there had been intervals of from six to eight weeks between periods; one interval lasted five months. The last period was three weeks before. Sometimes there was burning after urination and burning in the vagina. There was no history of vaginal discharge. One and a half years before, after urinating, the patient was seized with a sharp, knifelike pain in the right loin when she attempted to stand up. The pain began in front and radiated to the back. It was so severe that she fell to the floor. Following this attack, she was in bed for eight or nine weeks, and during this time was unable to move on account of the pain, which no longer was related to urination. Ever since then the patient had felt in danger of pain, sometimes with very acute attacks. During the intervals of comparative freedom she was able to bend forward and to move her trunk in any direction. During the past ten days, the pain had been severe, especially if the right arm was raised above the head, or if the right side was pulled or twisted. The pain was in the right side and back, but did not cross to the left of the spine. Frequently there was a dull ache in the spine, back of the head and chest which was unrelated to the pain in the lower back. This ache was worse in damp weather.

Periodicity: The patient had not been entirely well during the past five years. She always felt better in the autumn. Her symptoms all became most noticeable about December. During the past two years, she had been confined to bed during the late winter and spring, on account of the severe pain and general tenderness.

Physical Examination.—The patient was well developed and fairly nourished, conscious and rational, and lay quietly in bed with the eyes closed. The hair was abundant and of fair texture, but short, being only about 10 inches in length; the ends were broken off abruptly. The patient said that her hair used to be of finer texture and about 40 inches long. The skin was rather dry. On the face, most marked on the cheeks, there was a brownish-red pigmentation which was not sharply demarcated, but faded off gradually. There were many punctate papules; to the touch the cheeks felt like a nutmeg grater. On the back between the shoulders, there were small acneiform papules and pustules. There was a wart on the back of the left hand and on the palm of the right, which, the patient said, had been present for only a few weeks. The skin was otherwise negative. The conjunctivae were reddened and the patient kept her eyes closed most of the time because the light caused discomfort. The pupils were regular, equal, and reacted to light. The teeth were fair, the throat negative; the buccal mucous membrane was normal; the tongue was normal, except that the fungiform papillae at the back seemed unusually large and red. The lymph glands were not enlarged. The heart and lungs were normal. There was a slight general tenderness of the abdomen, most marked in the lower right quadrant. No masses were felt. There was no fluid. The patient had difficulty in turning over; the act seemed to be painful. There was no local tenderness in the back. There was no tremor of the hands. There was slight edema of the ankles on pressure. The knee jerks were very sluggish; the plantar reflexes also were sluggish. There was no Babinski reflex. The hand grasp was equal but weak. There was no Romberg sign. The finger-to-nose test was negative. The temperature was normal. The pulse was about 100. Pelvic examination was negative.

Summary.—A farmer's wife, aged 22, had been intermittently ill during the past five years, worse in the late winter and early spring. The outstanding symptoms were dermatitis with pigmentation of the face, muscular weakness, loss of weight, sore mouth, gastric discomfort, constipation, disturbances in taste, smell and cutaneous sensations, photophobia, menstrual irregularities, tachycardia, and many indefinite pains, aches and burning sensations. She had been unsuccessfully treated by many physicians and had tried all remedies that had been recommended by both physicians and friends.

Before the laboratory findings were considered, four conditions offered themselves as reasonable possibilities in the differential diagnosis. They all fairly adequately accounted for the symptoms as summarized.

1. Neurasthenia or psychoneurosis.
2. Pellagra.
3. Addison's disease.
4. Chronic arsenic poisoning.

Other conditions were thought of, such as renal stone and tuberculosis of the spine, but each accounted for only a part of the syndrome.

With a highly strung and unstable nervous system as a background, any chronic, unsuccessfully treated dermatitis may readily develop into an attack of neurasthenia with a varied host of symptoms similar to those described.[1]

Pellagra must be seriously considered, for it also is characterized by periodicity, weakness, neuritis, gastroenteritis, stomatitis and dermatitis. In the case under discussion, the chief point against pellagra is the character of the dermatitis. In pellagra, the backs of the hands and wrists are usually involved, and whatever region is involved shows a sharply demarcated area of pigmentation. Here the pigmentation is limited to the face, is diffuse, and is rather more finely papular than one would expect with pellagra.

---

[1] Osler: The Principles and Practice of Medicine, Ed. 8, pp. 1106-1116.

Addison's disease usually shows a more generalized pigmentation and frequently a pigmentation of the buccal mucosa.

According to the history as it was obtained after careful questioning on several occasions, the only known exposure to arsenic occurred five years before when the patient used arsenic sprays in fruit orchards. For the past three years, she had lived in a different place where there were no fruit trees, and she had not used any spraying mixtures. It is possible that some of her many remedies contained arsenic, but no single medicine had been used longer than a few weeks. Her brother's supposed appendicitis, which had been unrelieved by operation, and her sister's skin eruption suggest that the whole family had been exposed to arsenic.

Laboratory Examination.—Blood: 1. The systolic blood pressure was 120 and the diastolic, 85. This evidence points strongly against Addison's disease.

2. The Wassermann reaction was negative.

3. Microscopic examination revealed: white cells, 12,900; red cells, 4,500,000; hemoglobin, 95 per cent.; the red cells were normal: there were no malarial parasites.

Roentgen-Ray Studies: The teeth, spine, lungs and heart were all normal. There seemed to be some adhesions between the duodenum and gallbladder, but the stomach was otherwise negative; there was no filling defect, and the emptying time was normal.

Gastric Analysis: An Ewald test meal was given. After one hour, 100 c.c. of gastric contents were withdrawn. The odor was normal, there was no retained food, and microscopic examination was negative. Total acidity was 83; free hydrochloric acid, 51. There was no lactic acid nor blood.

Ophthalmoscopic Examination: This revealed dilated retinal veins and contracted arteries. These findings were regarded as unimportant and indicating merely vasomotor changes.

Stool: Macroscopically the stools were of a claylike consistency and rather gray. Microscopically there was bile-stained mucus, and no parasites or parasitic ova.

Urine: The urine was acid; the specific gravity was 1.017; there was slight trace of albumin; there were a few pus cells, red cells, occasional epithelial cells, hyaline casts and coarsely granular casts. A specimen submitted to the Kansas City Testing Laboratory for an analysis of metals was reported as containing: lead, 0; arsenic, 0.000329 per cent. Following this line of inquiry, a sample of wall paper and of well water from the patient's home were also tested for arsenic. The wall paper was found to contain arsenic (As_2O_3), 0.00307 per cent.; the well water was found to contain arsenic (As_2O_3), 0.00044 per cent.

DIAGNOSIS AND TREATMENT

The finding of arsenic in the urine, together with the typical symptoms of chronic arsenic poisoning make the diagnosis practically certain. The patient was once more questioned concerning a more recent exposure to arsenic. The husband then recalled that for the past two years he had used a Paris green mixture in spraying his potato plants. The patient remembered now that this mixture had been kept in a box in the kitchen, and to the best of her knowledge was still there. The fact that Paris green was kept in the house, and also the fact that the wall paper contained arsenic explains the winter exacerbations of all symptoms. At this time the patient spent more time indoors, and the windows were more likely to be closed; hence the greater opportunity to absorb arsenic vapors.

Undoubtedly the patient became thoroughly poisoned with arsenic five years before when she sprayed fruit orchards, and her illness had been prolonged by the subsequent absorption of small amounts of arsenic either from the box of Paris green or from the wall paper or from both. It is well known that in the presence of warmth and moisture, certain molds growing on arsenic wall paper liberate a poisonous volatile compound that is probably an organic derivative of arsenic pentoxid. According to Putnam,[2] "there is nothing more striking in the clinical history of this matter than the fact that a person who has once been poisoned, or who is naturally susceptible, is sometimes affected by exposures that seem absurdly insignificant." Putnam[3] also calls attention to the diffuse brownish pigmentation of the face, painful micturition, and distinctly periodic symptoms (winter and early spring) in addition to the commonly observed gastro-intestinal and nervous disorders.

The treatment consisted essentially in removing the source of poisoning and treating the gastro-intestinal disturbances symptomatically, with daily colonic irrigations of sterile water and a light diet of cooked food. According to latest reports a month later, the patient had improved markedly. The prognosis in this case is good because the peripheral neuritis has not progressed to an irreparable state.

CONCLUSIONS

This is a well marked case of chronic arsenic poisoning with an adequate etiology, and a definite finding of arsenic in the urine. The syndrome as developed here is remarkable for its multiformity. This patient showed loss of weight, muscular weakness, disturbances of the tactile and other special senses, digestive disorders, sore mouth and tongue with salivation, menstrual disorders, especially periods of amenorrhea, painful conjunctivitis, dry and defective hair, painful urination, tachycardia, loss of appetite, headache, diffuse pain and tenderness, and dermatitis which had been general, but at the time of examination was limited to the face and consisted of a roughening with diffuse brownish pigmentation. All of the symptoms were worse in the winter or early spring. When confronted with such a syndrome, one which is not typical of any well recognized disease, one should always think of chronic arsenic poisoning, and have the urine examined for arsenic by a competent laboratory, or by any one of several tests which are described in detail in textbooks on toxicology or industrial medicine.

Increased Importance of Venereal Prophylaxis.—The end of actual fighting in the world war does not lessen the necessity for the campaign against venereal diseases. Rather, it becomes a greater emergency measure than ever. Cessation of hostilities centers attention on the return of the victorious American forces. On entering the service the men became subject to Army and Navy discipline, which, in the control of venereal diseases within the ranks, is rigid. Prior to demobilization the intense fighting morale of the forces is bound to relax. The men will be buoyant in spirit and eager to celebrate. When mustered out they will return to conditions in civilian life which have been responsible for venereal disease. Many of them will contract it as a result. Unless all cases of venereal disease have proper treatment during the period of reconstruction, the scourge will reach alarming proportions. The time from now on is the most critical of all.—*Public Health Reports.*

TREATMENT OF TETANUS

REPORT OF CASE

MANUEL D. ROJAS, Ph.C., M.D.
Assistant Surgeon, Limón Hospital
LIMÓN, COSTA RICA

History.—N. B., a white man, aged 24, was admitted to the hospital, May 24, 1918, complaining of stiffness in his jaws, but still able to talk. He was a shoemaker, but for the past three months had been working as watchman at one of the railroad stations. The family history was negative. The patient had the usual diseases of childhood, had had gonorrhea twice, and a chancre about a year before. Recently he had been in perfectly good condition until about 3 o'clock on the morning of admission, when he awoke with stiffness of the neck, and had difficulty in opening his mouth. He said: "I have been in such good health that I expected to get married in a week." He did not recall any previous accident. There was no history of any cut or puncture for the past three months. On admission he was not aware of any fever, headache, languor or rigidity of the extremities. The bowel movements were regular, the appetite good, and there was no sore throat.

Physical Examination.—The patient was well developed. The head was negative; there was some rigidity of the neck, and there was slight spasms of the masseters. Although spasms of the jaws had already begun, I was able to remove the man's false teeth, and noticed an erosion in the upper gums, but no signs of local infection. The lungs were negative, but the patient complained of a heavy sensation in the lower part of the chest. The heart rhythm was regular. No enlargement and no murmurs were detected. The abdomen and the upper extremities were negative. In the lower extremities there was some rigidity and exaggeration of the reflexes, and Kernig's sign was present. I was unable to detect any erosion of the skin, except for that already mentioned, in the mouth. From the foregoing data it was clearly seen that no period of incubation could be appreciated in this case. On admission the temperature was 99 F., pulse 86, and respiration 22. The Laboratory reported that the urine was negative. The total white blood count was 8,463, the hemoglobin, 75 per cent.

Treatment and Course.—At the beginning I diagnosed tetanus. I ordered an intramuscular injection of 3,000 units of tetanus antitoxin, and gave 30 grains of potassium bromid every three hours.

I called Dr. A. A. Facio in consultation, and he agreed with me that the case was one of tetanus. He suggested that the tetanus antitoxin be given intravenously instead of intramuscularly, and also that potassium bromid and chloral hydrate, one-half ounce each, be given during the twenty-four hours by the rectal drip method.

In the evening of the day of admission the patient became worse, the rigidity of the neck and lower extremities more pronounced. Risus sardonicus was plainly shown, and the patient called attention especially to sharp lancinating pains at the base of the chest. I gave 5,000 units of the tetanus antitoxin intravenously. About 11:30 p. m., the patient became so distressed that it was necessary to give chloroform inhalations, and with this he rested somewhat. On the morning of the 25th, he presented a typical example of acute tetanus; orthotonus, opisthotonos and convulsive dysphagia were prominent symptoms. An enema was given, and good results were obtained. Intravenous injections of 5,000 units of tetanus antitoxin were repeated every six or eight hours, also the oral and rectal administration of potassium bromid and chloral hydrate.

This treatment was continued until the morning of the 29th, when the condition of the patient became so grave that some change in treatment was indicated. By this time the patient had received 68,000 units of serum antitoxin without having noticed any relief. Tetanus antitoxin, potassium bromid and chloral hydrate were discontinued. I was fearing some lung complication and for this reason also discontinued the chloroform inhalations. Baccelli's treatment was instituted. This consists in the intradermal injection of a 3 per cent. solution of phenol (carbolic acid) in water, 2 c.c. every three hours. The injections were given on each side of the spinal column, approximating more or less the exit of the nerve trunks. I also gave injections following the course of each sciatic nerve.

During the first ten days of Baccelli's phenol treatment, the intradermal injections were repeated as often as every hour with an average of about fourteen injections a day, that is, seven injections on each side of the spinal column. Later, as improvement began, the injections were given every two or three hours, applied mostly on the lower lumbar regions and along the course of each sciatic nerve.

The convulsive dysphagia and other painful symptoms, due to muscle rigidity, were treated by half a grain of morphin day and night with very good results, to the extent that the patient could have some rest.

I calculated that during the forty-seven days of phenol treatment, the patient was injected with about 450 c.c. of a 3 per cent. phenol solution, which is equivalent to 13.5 c.c. of pure phenol, without detecting any renal complications.

From May 28 to June 14 the patient was fed by rectum, and through the nares by means of a soft rubber catheter.

Besides the milk and other liquid foods, brandy was also given (about 2 ounces in twenty-four hours).

By June 15 the rigidity of the masseter muscles became much less and the patient was able partially to open his mouth. By June 26 he was able to open his mouth well and swallow the liquid food. The convulsive dysphagia was not so severe, but the rigidity of the lower extremities was still quite prominent. I found that the injections of phenol along the course of the sciatic nerves minimized considerably the painful rigidity of the lower extremities.

June 30 I discontinued the morphin and gave instead potassium bromid and chloral hydrate, 15 grains of each every four hours. This dose was now apparently sufficient to counteract nervous irritability.

All signs of muscular rigidity had disappeared by July 9, on which day I discontinued Baccelli's treatment and also the administration of potassium bromid and chloral hydrate. By this date the patient was emaciated, pale, and in a state of stupor, but he did not complain of any pains. Hemoglobin was only 55 per cent. A dose of calomel and magnesium sulphate was given, full diet was resumed, and 1 dram of elixir of ferric pyrophosphate, quinin and strychnin was given three times a day before meals. The patient recovered very rapidly, and was discharged, July 19, apparently in good condition.

The temperature during this time was 98 from May 24 to May 27; between 98 and 101 from May 27 to July 10; on the latter day it reached 103, and from July 11 to July 19 it was normal.

The highest rapidity of pulse and respiration was observed between May 27 and June 12, when the pulse rate was 110 and the respiration 28. It is worth while to notice that improvement began to be more rapid after June 11, when I added to the other treatment 10 grains of hexamethylenamin three times a day, and advised the patient to drink plenty of water. This increased diuresis considerably, and undoubtedly had something to do with a greater dilution and elimination of the tetanus toxin.

COMMENT

From this case we can see once more that the administration of antitetanic serum, once that the toxin has been fixed in the nerve cells, is of doubtful value either in preventing the further development of the disease or in minimizing its severity and duration. During the acuteness of the attack I found morphin superior to potassium bromid and chloral hydrate in relieving the painful muscular rigidity. It makes respiration easy, the patient sleeps better, and the nervous irritability is much decreased.

Baccelli's phenol treatment undoubtedly has an effect in neutralizing some of the tetanus toxin, and possibly inhibiting the growth of the bacillus. Diuresis, stimulated by the injection of fluids and the administration of hexamethylenamin, is useful because it diminishes the concentration of toxin products by a greater dilution and elimination of them from the body. Of course, the administration of large amounts of fluid to provoke diuresis depends on the condition of the patient's circulation.

METHOD FOR THE ISOLATION AND RAPID IDENTIFICATION OF DYSENTERIC BACILLI *

I. J. KLIGLER, Ph.D.
AND
PETER K. OLITSKY, M.D.
NEW YORK

Bacillary dysentery is endemic in the United States, and localized epidemics occur from time to time. Our Army and Navy particularly stand in danger from this disease. Of late, confusion has arisen regarding its etiology, as a result of the failure of the isolation of *B. dysenteriae* from the stools of patients. These factors have led us to devise an improved method of isolation and rapid identification of these organisms.

The failure on the part of some workers to isolate the true dysentery bacilli from cases of clinical dysentery is attributable largely to two factors: (1) the improper selection of stool specimens for cultures, and (2) the use of unfavorable culture mediums.

1. *Selection of Stool Specimens for Plating.*—Too much emphasis cannot be laid on the importance of choosing a satisfactory sample of stool. If possible, one containing blood and mucus with little or no fecal matter should be used. It is essential to plate the stool directly or very shortly after it is collected. Experiments with artificial mixtures of the Shiga bacillus with feces showed a 50 per cent. reduction in four hours and from 85 to 90 per cent. in twenty-four hours, when kept at room temperature.

2. *Mediums Used for Plate Cultures.*—Because of the extreme toxicity of dyes for dysentery bacilli, the selective inhibitive mediums used in the isolation of typhoid and paratyphoid bacilli are not applicable here. Consequently the medium most widely used in this country is Endo's, and in England, MacConkey's. The shortcoming of the Endo plate as originally proposed has been realized by workers in this field, and various modifications have been suggested. Kendal, Rettger and Robinson, Kligler and Defandorf successively proposed modifications. The first and last named authors recognized the fact that dysentery bacilli, particularly the Shiga variety, are highly sensitive to alkaline reactions and dyes, and are either partially or wholly inhibited on the original Endo medium, which is distinctly alkaline and contains an excessive amount of the fuchsin indicator.

The Teague and Clurman eosin-methylene blue medium with meat infusion as a base proved entirely unsatisfactory because of its inhibitive effect on Shiga dysentery bacilli. Recently, however, Meyer and Stickel have published comparative data indicating that the eosin-blue medium with veal-agar or pepsin-digest agar as a base gives better results than the Endo as modified by Kendal. The eosin-blue plate cultures show striking colony differentiation and have the added advantage of being at or near the neutral point. Comparative tests were made with various mediums, the results of which are shown in the accompanying table. The strains of the Shiga bacillus used were all isolated last summer and are undoubtedly more sensitive indicators of the favorableness of a given medium than old stock strains. The results indicate clearly that the veal infusion eosin-blue and modified Endo mediums are superior to the phosphate-peptone, the pepsin digest and the old unmodified Endo mediums. This superiority is also demonstrated when one compares the sizes of the colonies on the different plates.

COMPARISON OF RATIO OF B. COLI TO B. DYSENTERIAE COLONIES ON DIFFERENT PLATING MEDIUMS INOCULATED FROM THE SAME MIXTURES *

Medium Used	Flexner Strains						Shiga Strains				Average Size of Colonies in Mm.
	23	24	26	28	31	J	100	109	2X	V. T.	
Veal infusion eosin-methylene blue....	3:1	2:1	2.5:1	5:1	Spread	3:1	3:1	2:1	50:0	Crowded	1.5
Veal infusion Endo (Kligler's modification)........	3:1	1:1	3:1	1.5:4	Spread	5:1	3:1	Spread	50:1	Crowded	1.75
Veal infusion Endo (old method).....	4:1	48:0	7:1	5:1	48:0	35:0	200:1	40:1	200:0	2:1	0.5
Phosphate, eosin-methylene blue (Levine)........	2:1	2:1	5:1	3.5:1	2:1	6:1	50:1	4:1	17:1	1:2	1.0
Peptic digest, eosin-methylene blue (Meyer and Stickel)........	2:1	1:1	4:1	6:1	2.5:1	5:1	5:1	5:1	30:1	1:5	1.0
Peptic digest, Endo (Kligler's modification)........	4:1	1:1.5	7:1	Spread	4:1	3.5:1	2.5:1	2.5:1	36:1	1:2.5	0.8
Peptic digest, Endo (old method).....	Spread	1.5:1	7:1	Spread	4:1	....	3:1	6:1	33:1	Spread	1.0

* The figures indicate the ratio of the number of colonies of B. coli to those of B. dysenteriae. The marked inhibitive effect of the Endo medium prepared in the old way, titrating to +0.2 to phenolphthalein, on the Shiga types and the advantage of veal infusion medium are strikingly brought out in this table. "Spread" indicates that count was impossible as a result of confluence of colonies.

Practically, the slight inhibitory effect of the veal infusion eosin-blue medium on Shiga bacilli is overcome by inoculating this type of medium as well as the modified Endo medium[1] with the same specimen.

PROCEDURE

As a result of these tests, and experience in practical work and class work, we recommend the following procedure in the isolation and rapid identification of dysentery bacilli from stools:

A fresh specimen of stool, preferably with blood and mucus, is collected and promptly cultured. A shred of bloody mucus, if present, is selected, washed three or four times with sterile saline, to remove all fecal matter, and spread successively on a veal infusion eosin-methylene blue and a modified Endo plate. The plates are then incubated from eighteen to twenty-four hours at 37 C.

---

* From the Laboratories of the Rockefeller Institute for Medical Research.

[1] The modified Endo's medium is prepared as follows: To veal or beef infusion 1.5 per cent. agar, titrated, and this is important, to *pH* 7.6 to 7.8, is added 1 per cent. lactose and 1 per cent. by volume of decolorized basic fuchsin indicator. The latter is prepared by adding 1 c.c. of 10 per cent. basic fuchsin to 10 c.c. of 10 per cent. sodium bisulphite solution. Of course, the lactose and the indicator are added separately before plates are poured.

The eosin-blue medium is prepared by adding to the veal infusing agar titrated to *pH* 7.2 to 7.4, 1 per cent. lactose and 2 c.c. of a 2 per cent. solution of yellow eosin and 2 c.c. of 0.5 per cent. solution of water-soluble methylene blue.

The plates are now examined and the suspicious, colorless colonies inoculated into each of two differential tubes:

(*a*) A small tube containing 1 c.c. of a 0.5 per cent. glucose broth.

(*b*) A double sugar tube on the principle of the Russell double sugar medium containing 0.1 per cent. glucose, 0.5 per cent. mannite, and 1 per cent. Andrade indicator.

The colony is picked off with a small loop and inoculated first into the broth and then stabbed in and streaked on the double sugar tube.

After from two to four hours the broth tubes are usually sufficiently turbid for an agglutination test with a polyvalent antidysenteric serum. A faint visible turbidity is sufficient, and when it appears, 0.1 c.c. of a 1:50 dilution of a potent polyvalent antidysenteric serum is added and the tubes reincubated for one hour. A definite clumping is a good presumptive test for the presence of dysentery bacilli.

The double sugar tube is incubated over night. A red butt without gas and colorless slant indicates a Shiga bacillus. If the entire tube is red and gas absent, it corresponds to a Flexner type. The surface growth is now washed off with saline and a confirmatory agglutination test is made with specific type and polyvalent serum. If desired, an agar slant and various sugar mediums may be inoculated for further study, or animal inoculation made.

By the use of the two tubes, one can obtain a presumptive diagnosis about a day after the collection of the stool—a matter of great importance for epidemiologic and therapeutic purposes.

CONCLUSIONS

1. Fresh specimens preferably containing blood and mucus should be cultivated promptly.

2. Mediums for the isolation of dysenteric bacilli should not have a marked alkaline reaction or an excessive amount of inhibitive dyes. Mediums neutral or only slightly alkaline are most suitable. Veal infusion agar is a much more satisfactory base for differential plate cultures for the isolation of dysenteric bacilli than is beef infusion or peptic digest agar. Eosin-methylene blue and modified Endo plates (*p*H 7.6 to 7.8) made with veal agar exert little or no inhibitive effects and permit the colonies to grow to almost twice their size on other mediums. Since the dye medium is apt to be somewhat inhibitive for the Shiga type of dysentery bacillus, it should always be used together with a modified Endo plate.

3. The method given permits a presumptive and confirmatory diagnosis of bacillary dysentery in a very short time.

Regulating the Distribution of Quinin.—The Brazilian government has promulgated regulations for the purchase and sale of quinin for use in overcoming destructive endemias in the rural sections. The drug will be purchased either in foreign or domestic markets in the shape of salts of quinin, and cinchona bark will also be imported and extracted in the Oswaldo Cruz Institute. When prepared the quinin will be sold in tubes officially sealed with a government stamp and marked with a label indicating the quantity, quality and official price. The tubes will be furnished to pharmacies and to other distributors, especially throughout the malarial sections of the country, with the requirement that they shall not be sold at a profit exceeding 10 per cent., under penalty of fine for violation of the price regulation. According to *Commerce Reports*, from which this information is obtained, the federal railways will be furnished the official quinin and will distribute it without cost to employees. Other industries may purchase it for free distribution at a rebate of 10 or 20 per cent.

THE EFFECT OF "GROUND GLASS" ON THE GASTRO-INTESTINAL TRACT OF DOGS

JAMES S. SIMMONS, M.D. (PHILADELPHIA)
Major, M. C., U. S. Army
AND
WILLIAM C. VON GLAHN, M.D. (BALTIMORE)
First Lieutenant, M. R. C., U. S. Army
FORT SAM HOUSTON, TEXAS

During the past few months quite a number of food specimens have been received at the Southern Department Laboratory, Fort Sam Houston, Texas, with requests for examination to determine the presence of "ground glass."

Of 120 specimens of different kinds, glass was found in the following samples: cakes, 2; cottonseed hulls, 5; jelly, 1; milk, 1; prepared mustard, 1; peanut butter, 1; sliced beef, 1, and sugar, 1.

The glass found in many of these specimens was small in size and amount, and could have been accidental. Some few samples of food in closed nonsealed containers, however, showed many large pieces of broken glass, which, apparently, had been placed there purposely by those sending in the specimens.

Many reports of so-called "glass poisoning" were made by newspapers and individuals, and the subject was discussed in a number of medical journals throughout the country, but we have not been able to obtain positive data concerning a single authentic case of illness due to the ingestion of glass in any form or size. A partial review of the literature gave no definite information.

FEEDING EXPERIMENTS

In an attempt to determine what lesions, if any, are produced by glass in the gastro-intestinal tract, feeding experiments were carried out on dogs.

Dogs.—Ten young dogs obtained from the city pound of San Antonio, Texas, were placed in separate cages, numbered, and fed on scraps from the hospital mess. Records were made of the general appearance, weight, temperature (by rectum), blood count and feces examination (both gross and microscopic) for blood, pus, epithelium, etc. All these records, with the exception of blood counts, were made daily, until the completion of the experiments, when the animals were chloroformed and examined postmortem.

Glass.—Broken Petri dishes and test tubes were ground in a large stone mortar, after which the glass was divided into five sizes by passing through sieves of different mesh. The different grades of glass used ranged from Grade 1, which was designated "large broken," to Grade 5, called "fine powdered." A large amount of each grade was prepared and bottled.

Dosage.—The ten animals were divided into two series of five each. Dogs of Series 1 received 1 gm. of the grade of glass corresponding to the cage number, while Series 2 (Dogs 6 to 10) received 5 gm. doses in the same order. Thus, Dogs 1 and 6 received Grade 1 glass, but Dog 6 received 5 gm., while Dog 1 was only given 1 gm. doses.

Each dose of glass was mixed in a mortar with about 200 gm. of lean meat and immediately fed to the dog. All grades, except Grade 5, were easily detected in the food with the naked eye. The first two doses were given at four-day intervals, but after that they were repeated daily until the animals were chloroformed. (The second dose in each case, owing to a mistake, was of different grade glass.)

Weights.—The original weight was accepted in each case as normal, and the fluctuations that were recorded represent merely loss or gain in pounds.

The weight curve in each case showed fluctuations, and in five of the dogs there was a slight loss of weight as shown on the day of necropsy, averaging about one-half pound. Two of the dogs showed marked gain in weight, and in three the initial and final weights were identical.

Temperature.—These records by rectum showed nothing remarkable except in Dog 5, which had a temperature of 104 F. on two occasions: May 21, twenty-four hours after receiving the first dose of glass, and May 24, when the second dose of glass was given. The rise in temperature was probably due to some other cause, as it was only temporary and as Dog 10, which received five times as much of the same grade of glass, was not similarly affected.

FLUCTUATIONS IN WEIGHT

Number of, Animal	Weight Gained	Weight Lost
1	....	½ pound
2	....	½ pound
3	None	None
4	3 pounds	
5	None	None
6	....	½ pound
7	....	1 pound
8	....	½ pound
9	1 pound	
10	None	None

Number of animals that gained weight	2
Number of animals that lost weight	5
	Pounds
Average weight gained	6
Average weight lost	6

Feces.—All daily examinations were negative for blood and pus. Dog 5 showed a slight temporary diarrhea with some mucus at the time of the rise in temperature, after which the stools were negative. Practically all the dogs were infected with *Uncinaria* and *Taenia*.

Necropsy Findings.—The dogs were killed with chloroform and immediately examined. The postmortem findings were remarkably uniform in the absence of any visible lesions. As the findings were so similar, detailed account of each will be omitted and one protocol given:

> The peritoneal surfaces are smooth and glistening and there is not any excess of fluid in the peritoneal cavity. The omentum contains much fat. The intestines are not distended. The lymphatics are engorged and beautifully marked out so that they are easily traced from the intestine through the mesentery to the glands. The stomach contains a large amount of undigested food in which particles of glass are readily discernible. The gastric mucosa is gray and translucent. There is no ulceration nor any evidence of hemorrhage. The intestine contains a moderate amount of digested food in the upper half. The intestinal mucosa is gray and translucent, and there is no ulceration, hemorrhage or exudate present. There are several taeniae and many uncinariae present in the lower portion of the bowel. The lungs, heart, spleen, pancreas and liver are negative.

The postmortem findings in the control dogs were identical, except for the absence of glass.

For the microscopic preparations from six to twelve segments of the intestine from different portions were removed before the bowel was opened. This was done to avoid the possibility of any trauma to the mucosa while opening the bowel. These segments measured from 5 to 10 mm. in length. The stomachs were opened before the specimens for microscopic examination were removed. The tissue for examination was immediately placed in 10 per cent. solution of formaldehyd. The paraffin method was used in the preparation of the material for sectioning.

The findings microscopically were equally negative. The sections from the stomach of each of the dogs and from the control dogs did not show any abnormal changes. The epithelium was intact and there was not seen any infiltration with leukocytes or small round cells of the mucosa, submucosa or muscular layers in some of the sections. From the intestines of four of the dogs (3, 4, 6 and 7) there was seen some denudation of the tips of some of the villi of their epithelium. There was not, however, any exudate on the surface of the villi, or any inflammatory reaction within them. No other abnormal changes could be found in any of the sections. The central lacteals and lymphatics were engorged in those dogs that were examined during the period of active digestion. The gross and microscopic findings were identical on the dog that was given one large dose of glass (50 gm.) and examined postmortem forty-eight hours later.

In both of the control dogs, denudation of the tips of some of the villi of their epithelial cells was observed.

CONCLUSION

The ingestion of ground or powdered glass has no toxic effect and produces no lesion, either gross or microscopic, on the gastro-intestinal tract of dogs.

OBSERVATIONS ON AN EPIDEMIC OF BRONCHOPNEUMONIA IN OMAHA [*]

A. D. DUNN, M.D.
OMAHA

Late in September and in the early days of October, a respiratory affection corresponding somewhat closely to the descriptions given of "Spanish influenza" appeared in Omaha. October 3 and 4, a large number of people congregated in the theaters, stores and streets, incident to the civic parades and other functions of the Aksarben festival, which yearly brings huge crowds to Omaha. October 5 and 6, the disease attained the proportions of an epidemic. We also have information that a considerable number of cases appeared among the troops in Fort Omaha on the second day following the Aksarben. The morbidity curve showing the influence of "crowds" on the outbreak of the epidemic is significant (Chart 1).

THE NATURE OF THE EPIDEMIC

Clinically, the disease was characterized by a more or less sudden onset, usually without definite prodromes. Headache, generally severe, was almost constant and commonly associated with backache, boneache and general malaise. Cough, which was slightly productive or nonproductive in the beginning, was always present. The sputum was not tenacious but mucoid. Its color varied from a slight, diffuse, bloody discoloration to a deep bloody red. The sputum never took on a typical rusty appearance. Toward the end of the disease a suggestion of rustiness was occasionally present. Cyanosis was uniformly present and was disproportionate in degree to the severity of the disease except in the moribund. The temperature curve was either of the remittent or the continuous type. Reverse types were common. Drops of lysis predominated (83 per cent). Considering the severity of the symptoms, the pulse was slow except in the moribund. Death seemed rather of a respiratory than of a cardiac type. Delirium was usually absent. Gastro-intestinal symptoms were common (50 per cent). Herpes was rare. The most constant feature was the presence of findings pointing definitely to pulmonary involvement. The lungs of all the patients under observation were examined at least once a day, and whenever any change in the pulse-temperature curve or in the clinical course occurred. In no instance was a typical "flu" case of any considerable duration observed that did not at some stage of the disease reveal lung findings, such as signs of increased density to palpation and percussion, altered breath sounds, or localized moisture evidenced by fine or small moist râles. Lung findings diagnostic of bronchopneumonia were absent in only 18 per cent. of the hospital admissions. The latter cases were in all instances mild, being of from one to three days' duration. Pleurisy was exceptional, although pains in the chest were common. Although the observations were made largely in hospital cases, and although it might be argued that only the severe cases would gravitate to the hospitals, yet whenever accurate clinical observations were made, they supported the assumption that we were dealing with an *epidemic of bronchopneumonia*.

---

[*] This investigation was made by the University of Nebraska and Creighton Medical colleges at the instigation of the Omaha Department of Public Health.

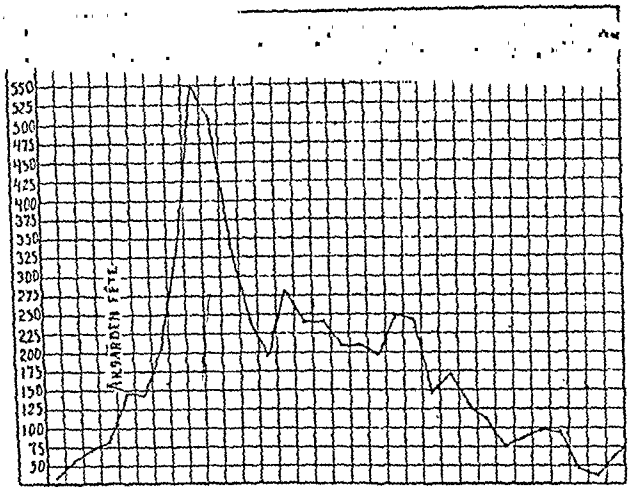

Chart 1.—Morbidity curve showing the influence of "crowds" on the outbreak of influenza.

Two hundred consecutive leukocyte counts averaged 11,950 cells with 72 per cent. polymorphonuclears. The leukocyte count seemed at times to have prognostic worth. Low leukocyte counts occurred most commonly in the severer cases. Rises in the leukocyte count often presaged improvement, and sharp drops in the count were ominous. Chart 2 illustrates a typical leukocyte curve in a fatal case.

An interesting fact was the relative infrequency in the disease history of the patients of antecedent respiratory infections, as bronchitis, tuberculosis, catarrh, nasal disease, diphtheria, pneumonia or pleurisy. This is suggestive of a degree of active immunity in individuals who have previously suffered from respiratory disease. Fatalities were most common among the robust. The average age of our patients was 23.5 years.

ETIOLOGY

Bacteriologic studies were carried out on material derived from sputum, blood cultures, necropsies and pleuritic exudates. Smears and cultures constantly revealed a diplococcus resembling in many ways the pneumococcus, but giving atypical cultural reactions. The organism was gram-positive, with a tendency to short chain formation. Capsules could not be definitely demonstrated with the usual capsule stains, but a suggestive halo was frequently encountered. The growth of the organism on ordinary culture mediums was exceedingly difficult, and even on special mediums the growth was decidedly delicate. Litmus milk containing blood and blood agar proved most satisfactory. Many strains refused to grow beyond several transfers. The original cultures coagulated milk in forty-eight hours, which reaction often failed to occur after several transfers, the organism frequently dying out even when transferred every three to four days on blood mediums. Bile solubility was variable (positive in 40 per cent). Inulin and litmus milk were usually acidified and coagulated. Mice were decidedly susceptible, and died in from twelve to eighteen hours after intraperitoneal inoculation, and the organism was constantly recovered from the heart's blood. The virulence of the organism diminished rapidly when grown on artificial mediums, and several transfers usually sufficed to render it avirulent. Only a limited number of strains have been typed, but the majority of these have failed to agglutinate.

Every effort was made to recover other types of organisms, especially the Pfeiffer bacillus, but without success. Anaerobic and varying oxygen tension cultures after Rosenow's method were made as a routine. It is of interest to note that positive blood cultures were obtained as a rule only at the height of the disease, and then only in the moderately severe or in the severe cases. This is suggestive of a descending respiratory rather than a hematogenic mode of infection.

All the necropsies thus far made have shown a bronchopneumonia of a hemorrhagic type except in one instance in which the pneumonia was of the typical lobar form, and the organism isolated from the blood culture and at the necropsy proved to belong to the Type II pneumococcus. It was noted clinically that this case was probably an ordinary pneumonia and was not of the prevailing epidemic.

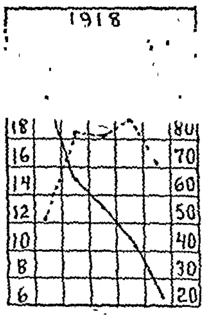

Chart 2. — Typical leukocyte curve in a fatal case of bronchopneumonia. The column at the left gives the number of leukocytes in thousands, and is represented by the solid line; the column at the right, the percentage of polymorphonuclears, and is represented by the broken line.

CONCLUSIONS

1. The clinical and laboratory observations made to date go far to support the assumption that we are dealing in Omaha with an epidemic of atypical bronchopneumonia. It would be reasonable to assume that in mild cases which do not develop demonstrable lung disease (and from our experience they must be rela-

tively few) there is a partial active immunity which accomplishes an early abortion of the disease, or that the infecting organism was avirulent. We consider bronchopneumonia the one characteristic clinical and pathologic finding in our epidemic (82 per cent.) In other words, *the so-called complication is the disease.*

2. Bacteriologic examinations thus far made reveal an organism which seems best classified as an atypical pneumococcus and which we consider to be the probable cause of the epidemic.

Further clinical, bacteriologic and immunologic studies are under way.

PHLEGMONOUS GASTRITIS

REPORT OF CASE

F. I. SHATARA, M.D.
BROOKLYN

Phlegmonous or submucous gastritis is a rare condition. It was first described by Benel in 1656. In 1904, Robson and Moynihan collected eighty-five instances, and up to the present about 100 cases in all have been reported.

The condition is an acute suppurative inflammation affecting oftenest the submucous coat of the stomach, and extending to the muscular and serous coats more frequently than to the mucous. It is sometimes primary, but usually secondary, occurring in the course of such diseases as typhoid, scarlet fever, smallpox or puerperal septicemia. Two forms have been described, a diffuse and a circumscribed.

The etiology is not definitely known. Of the several theories that have been advanced, the bacterial seems to be the most plausible. Streptococci are the commonest micro-organisms present; colon bacilli have been occasionally demonstrated. In the case here reported, streptococci were demonstrated in the stomach wall by the Gram-Weigert stain. In secondary cases it is probable that the infection is carried by the blood stream. It is held by some that the invading organisms enter through traumatic or other lesions in the epithelium. Symmers, at Bellevue Hospital, however, failed to produce the lesion in animals by feeding them ground glass and inoculating streptococci and pneumococci by way of the blood stream or stomach tube, and the association of phlegmonous gastritis with such lesions as ulcer and cancer is almost unkown. The pyloric region of the stomach seems to be the site of predilection, although the process may involve the entire stomach.

The onset is sudden with symptoms of intense gastric irritability and profound general disturbances. The issue is rapidly fatal. Sometimes the symptoms of general peritonitis, as in the case here reported, are superimposed, and it is probable that many cases are similarly obscured and thus wrongly diagnosed.

Pain, epigastric tenderness, nausea, vomiting, chills, fever and hiccup are the outstanding symptoms. Hiccup was marked in the present case.

The course is usually from one to seven days.

The diagnosis during life is at best a guess. Chvostek is said to have succeeded in making one such diagnosis.

REPORT OF CASE

History.—C. W., man, aged 29, married, colored, laborer, American, applied for treatment at the dispensary, Dec. 19, 1917, complaining of a vague abdominal pain, general in character, intermittent in type, increasing usually after meals, but never severe enough to confine him to bed or to interfere with his appetite. The patient was constipated. There was no history of vomiting, gaseous or sour eructations, or jaundice. Physical examination revealed a slight abdominal tenderness, more marked on the right side, but no masses and no rigidity. Over the aortic area there was a faint systolic murmur transmitted to the carotids, but no other signs of cardiac trouble. The patient was advised to enter the ward for observation, but refused.

December 26, he returned to the dispensary, complaining of the same vague abdominal pain. He was again advised to enter the ward, and the withdrawal of blood for a Wassermann test was suggested, but he refused both.

Present Illness.—On the morning of Jan. 19, 1917, the patient awoke with a headache, and was unable to take his breakfast; this he interpreted as a sign of severe illness. He applied to the dispensary at 9 a. m., and was given half a grain of codein and ordered to bed. At 10 a. m. he vomited and complained of pain in the epigastrium. At 4 p. m. his condition grew worse, the abdominal pain increased, nausea became distressing, and he vomited again. The vomitus was brownish in character, mixed with mucus, but free from blood or pus. Physical examination revealed general abdominal tenderness and rigidity, more pronounced on the right side. There were no signs of free fluid and no obliteration of liver dulness. The facial expression was anxious. The patient had a leukocyte count of 15,000, temperature of 101.6, pulse 100, and respirations 22. A ruptured gastric ulcer was suspected and he was admitted to the male surgical ward of the Englewood Hospital under the writer's care.

The patient slept about seven hours during the night. Next morning he repeatedly vomited green fluid. At 8 a. m. he had a leukocyte count of 27,400; polymorphonuclear neutrophils, 92 per cent.; lymphocytes, 8 per cent.; temperature, 103.2; pulse, 108, and respirations, 24.

He was operated on at 11:30 a. m., by Drs. Bradner and Pitkin. About 2 ounces of serosanguineous fluid were found in the peritoneal cavity. No definite perforation was located. A posterior gastro-enterostomy was impossible on account of excessive thickening of the stomach wall. A gastrostomy was performed, and it was noted that the stomach wall had lost its elasticity and had become so indurated that it was difficult to suture it to the gastrostomy tube. Two cigaret drains were inserted into the peritoneal cavity, and the patient was returned to bed. His general condition was fair, pulse 116, respiration 24. The rectal drip was employed and pituitary solution given.

About 11 p. m. the patient became very restless and thirsty, and complained of pain in the operative area. He also had a hiccup and there was a bloody discharge on his dressing. An irrigation with warm saline through the gastrostomy tube was performed; the return was at first bloody but later became clear. The temperature was up to 104.4, pulse 128, respirations 26. He slept about four hours subsequently.

Next morning, nutritive enemas were started.

In the drainage bottle to which the gastrostomy tube was connected there were 16 ounces of wine colored fluid.

About 8 a. m. the patient's temperature went down to 102, and his pulse to 118, but his respirations were accelerated to 32. At 3 p. m. the abdomen was distended and tympanitic, but there was no evidence of free fluid. He was given an alum enema with good result.

His general condition grew worse, his pulse rose to 138, and became thready, he was given stimulation but did not respond, and he died at 7:50 p. m.

Necropsy.—This was limited to the abdomen. There was about 1 quart of bloody fluid in the general peritoneal cavity. The fluid had apparently oozed through numerous minute perforations in the stomach.

The stomach wall was greatly thickened, measuring from a third to half an inch, and on compression, gastric contents oozed through several pin-point-perforations. These perforations were clearly demonstrated by opening the stomach and holding it up against the light. The gastric mucosa looked and felt leathery and smooth, the rugae having been obliterated. The process was diffuse.

The intestine was distended, and the intestinal wall was slightly congested. The mucous membrane was normal. The mesenteric nodes were enlarged.

The liver was pale and opaque; its substance was soft and mushy, reminding one of the liver in cases of acute yellow atrophy. The splenic tissue appeared normal except for a slight congestion.

The remaining organs were negative.

Numerous microscopic sections of the stomach were prepared in the pathologic laboratories at Bellevue Hospital. They were examined by Dr. Symmers, who found that the mucosa of the stomach was normal except for a superficial necrotic layer. The entire stomach wall beneath the muscularis mucosae was richly infiltrated by polymorphonuclear leukocytes, and was markedly edematous. The blood vessels of this portion of the stomach were deeply injected. Gram-Weigert preparations revealed the presence of innumerable streptococci lying chiefly in the stomach wall immediately under the muscularis mucosae. Microscopic sections from the intestinal tract revealed no pathologic changes.

THE INCIDENCE OF TYPHOID CARRIERS IN A STATE INSANE ASYLUM*

CHARLES KRUMWIEDE, Jr., M.D.
BRONXVILLE, N. Y.
AND
ELBERT M. SOMERS, M.D.
BROOKLYN

In September and October, 1907, the Brooklyn State Hospital had some cases of typhoid fever. At this time, Drs. Smith and Agnew of this institution sent to Miss W. Carey Noble, of the Bureau of Laboratories, the stools of all the convalescent patients; continued examinations showed that two women (E. O. and A. M.) had become chronic bacillus carriers. In 1912, there were a few cases of typhoid fever, and from these developed another chronic carrier (M. R.). Again, in 1915, a few inmates contracted the disease.

As previous reports have shown the tendency to a high carrier rate in asylums, we thought it worth while because of this history of institutional fever, to cooperate in a survey to determine the incidence of typhoid carriers. Under the direction of one of us, the institution was listed by wards, and ward residence since 1907 indicated for each inmate. Our intention was to include only the resident population at the time these lists were compiled. Specimens of feces were collected and brought to the laboratory as soon as possible after evacuation, and were there examined for the *Bacillus typhosus*. All the inmates in the female wards have been examined, yielding the following results:

Wards 1 and 2, population (February, 1916), 91: No cases of typhoid developed in this ward. One resident had typhoid in Ward 9 in 1907. No carriers were found.

Wards 3 and 4, population (March, 1916), 65: There were two cases of typhoid in this ward in 1907, and both the patients became carriers (E. O. and A. M.). Two additional carriers (M. C. and H. G.) were found, both without a history of typhoid. M. R., a chronic carrier, who developed typhoid in Ward 9 in 1912, was transferred to this ward later in the same year, and died here in September, 1915.

Ward 5, population (April, 1916), 80: One case of typhoid developed in 1907. Another patient had typhoid in Ward 9 in 1912. No carriers were found.

Ward 6, population (April, 1916), 132: No cases of typhoid developed in this ward. No carriers were found.

Ward 8, population (April, 1916), 72: No cases of typhoid developed in this ward. Three residents gave histories of typhoid, two before admission to the hospital, one in 1907 in Ward 9. Examinations were negative. Two carriers (J. M. and M. W.) were found, both without a history of typhoid. M. W. died in February, 1916. The changes in ward residence of these carriers and of other carriers, then unrecognized, may have led to contact infection and the development of the carrier state, without recognizable symptoms of typhoid infection.

Ward 9, population (May, 1916), 76: Eight cases of typhoid have developed in this ward: two in 1907, four in 1912, and two in 1915. (Three of these persons are now residents in other wards, and noted there.) One 1912 patient (M. R.) became a chronic carrier and was transferred to Ward 3 (which see). Examinations of the four residents were negative. One typhoid carrier was found (M. B.) who denies a history of typhoid fever.

It will be seen from this summary that, in a total population of 516 female patients, the survey yielded five chronic carriers, in addition to three previously known. Of the last, all continued to excrete bacilli after having had typhoid fever, two in 1907 and one in 1912. Of the other five, none gives a history of typhoid fever. Too much reliance cannot be placed on negative histories of typhoid fever, especially from patients of this type, as the symptoms of a mild infection may have been overlooked.

In spite of this, however, we believe that it is not an unreasonable assumption that some of these patients coming in contact with cases or carriers ingested the bacilli, became normal or contact carriers, and later developed into chronic carriers. That is, their natural immunity prevented the development of a generalized disease; but in spite of this resistance, the bacilli multiplying in the intestine, small numbers may have invaded the body proper and through the lymphatic and vascular systems may have reached the liver and gallbladder, where they localized and gave rise to chronic inflammation. After their localization in the biliary passages, a chronic carrier state would be likely to result.

The striking thing in this investigation is the large number of carriers, eight among 516 persons, or 15.5 per thousand. This rate is higher than usually encountered in institutions and much higher than among the general population. The unusually high incidence is shown by applying the rate to the female population of New York State over 25 years of age. This would give the extraordinary result of 45,000 carriers.

In view of these results as well as because of the frequency of institutional typhoid fever, we do not believe that any one would question the advisability of vaccination of all inmates of insane asylums. Unfortunately, however, this procedure is left to the discretion of the institutional authorities and is not carried out as generally as it should be.

A considerable amount of institutional typhoid fever due to the failure to vaccinate has come to our notice during the last few years. Because of this, we feel that vaccination should be mandatory not only in asylums but also in all custodial institutions, and a regulation to this effect should be added to the sanitary codes of all health departments.

Military Medicine and Surgery

THE EFFORT SYNDROME

TOGETHER WITH A CONSIDERATION OF THE SIGNIFICANCE OF CERTAIN MURMURS *

ALFRED E. COHN, M.D. (New York)
Major, M. R. C., U. S. Army; Senior Consultant in General Medicine, A. E. F.
FRANCE

The war has altered opinion of the value of many signs formerly accepted as important indications of the presence of organic heart disease. The chief sign involved in the changed point of view is the systolic murmur. The significance attached to diastolic murmurs, both the diastolic murmur of aortic insufficiency and the presystolic murmur (auriculosystolic) of mitral stenosis, has remained unaltered. Persons affected with these two diseases have been found not to bear the strain of war satisfactorily, even if at the time of enlistment they were free of any indication of heart failure. They are now, accordingly, rejected for service.

The significance of systolic murmurs, especially their relation to mitral insufficiency, however, has occasioned much discussion. Systolic murmurs occur in so large a number of persons that it has become necessary to decide when they are important and denote mitral insufficiency. The need for making the distinction between important and unimportant systolic murmurs occurred infrequently in civil life. Young men rarely sought medical advice on account of such murmurs. When they did, as the result of life insurance or other accidental examination, the difficulty in diagnosis was appreciated, but reliable guides for making a decision were wanting. Early in the war, men with such murmurs were accepted, and many were found after severe service to bear satisfactorily the fatigue incident to campaigning. The conclusion was therefore drawn that the murmur in itself must in these instances be considered unimportant. New criteria were accordingly required to decide which systolic murmurs were important and which types were not.

CLASSIFICATION OF SYSTOLIC MURMURS

Until now, it has been customary to divide murmurs into two groups, functional and organic. To decide in which group a murmur belonged, it was studied from the point of view of the bearing on it of the posture of the body, of the position in the precordial area at which the murmur was best heard, of its character on auscultation, according to its intensity in different respiratory phases, according to the direction of its transmission, and according to its time incidence in the cardiac cycle.

A word should first be said on the use of the words "functional" and "organic" in relation to murmurs. A murmur is, of course, a physical phenomenon and is dependent on the structure of the containing vessels and the arrangement of the surrounding tissues for its production and character. This is true of the so-called functional murmur as well as of the organic variety. All murmurs are in this sense organic. The distinction that the words "functional" and "organic" were intended to convey relates to their importance or unimportance, or perhaps better to their significance or insignificance. The point is in itself not important except in the interest of clear understanding.

Close study has failed to show that systolic murmurs may be classified as significant or insignificant according to the criteria just enumerated, that is to say, posture, position, character, respiratory emphasis, transmission, and position in the cardiac cycle. It is, of course, true that aid may be obtained from certain of these criteria; but the aid is not definitive. Other criteria have therefore been proposed. These relate (1) to the size of the heart; (2) to the history of infection, especially of rheumatism; (3) to the intensity of the second sound in the second left interspace or third left costochondral junction, and (4) to the reaction to exertion. A candidate may be accepted for service in the Army if his heart is normal in size, if there has been no history of rheumatism, if the second cardiac sound is not accentuated, and if the response to a standard exercise test is normal, even though a systolic murmur is present. The terms used require explanation.

The heart is normal in size in adult males in civil life in the third decade, when in the oblique position it measures from 9 to 11 cm. In active military service the size often increases to from 11 to 13 cm., and these dimensions are considered normal. The measurements given are based on roentgenograms placed when exposed 2 meters from the target of the roentgen-ray tube. Attention must be called in this connection to the fact that not all normal hearts lie in this oblique position in the chest. Frequently their outline shows them to have a more vertical position in the midthoracic region. Sometimes they have a more nearly transverse position. These variations naturally make the diagnosis of hypertrophy difficult and must be taken into consideration in deciding on its presence. A hypertrophied vertical heart may in profile be smaller than a normal transverse organ. In every instance, therefore, a correct estimate of size may not be possible.

The second criterion mentioned is the history of infection, and especially rheumatism. Under rheumatism are included acute rheumatic fever, chorea, torticollis, tonsillitis and growing pains. It is obvious that a single attack of acute rheumatic fever occurring in childhood, and being followed by no obvious cardiac disability, is not as important as repeated attacks, the last of which has occurred within the year.

The third criterion relates to the intensity of the second sound. It is not possible to state that the second sound is invariably accentuated when chronic mitral endocarditis has persisted for a prolonged period, but it is believed to be the rule that after long-standing disease an accentuation takes place. Its presence is therefore of significance in deciding that disqualifying disease has occurred.

The nature of the response to a standard exercise test is the fourth criterion. The introduction of the test is important, for it gives information of what one desires to know as the result of examination, that is to say, the ability to undergo exertion. The test recommended in Circular 21, of the Surgeon-General's Office, consists in hopping 100 times on the left foot so that the shoulder is elevated from 4 to 6 inches. Two minutes after the end of this exercise, the ventricular rate should return to approximately within ten beats of normal and the blood pressure to normal. The

---

* Lecture delivered at the Army Sanitary School, A. E. F., April 29, 1918.

measurements are made with the patient in a recumbent position. The test is recommended because it is simple and can be carried out in a uniform manner.

It is not pretended that one can rely on these criteria always to solve a difficulty in diagnosis when a systolic murmur is present. But they are useful when, in addition to the murmur, the heart is barely enlarged and a history of repeated and recent attacks of rheumatic fever is reported.

A word should be said about the character of the apex impulse. It has been the habit to lay stress on its extent and position and on the force or other slight abnormalities presented by it on palpitation. Recently abundant experience has tended to confirm the impression that too much stress is laid on these phenomena. But as an indication of the position of the left border of the area of cardiac dulness, in estimating hypertrophy, the location of the apex, especially its farthermost extension to the left, is valuable.

EFFORT SYNDROME

These views as to the systolic murmur represent the chief alteration that has been made in the point of view of organic heart disease. Of far greater importance is a syndrome, functional in nature and, although not confined to soldiers, especially common in war. It is a group of symptoms, referred by soldiers to the cardiovascular system, and forming a frequent cause of more or less serious disability. This group of symptoms was first described as a clinical entity during the Civil War in the United States by Hartshorne, and the description was later elaborated in greater detail by DaCosta. By the latter it was called the "irritable heart of soldiers," and the disorder was known by this name until the present war.

The reason for its occurrence was sought in our own and other armies. Its cause was laid first to one and then to another circumstance. It was found everywhere and under all conditions. During the present war, attention was forcibly directed to the affection because of the large numbers of soldiers whom it involved. With the new work on the subject, the name of Thomas Lewis is closely connected. His recommendation that the affection be known by the term "effort syndrome" has fortunately been accepted in the American Expeditionary Forces. It is classed in the British service as disordered action of the heart (D. A. H.).

The affection is characterized principally by the occurrence of breathlessness, giddiness, a sense of fatigue, pain in the chest, often in the region of the precordium, and palpitation. On examination are found, in addition, an anxious facies, tremor or shakiness of the fingers alone or of the extremities or even of the whole trunk, cyanosis, sweating, skin hypersensitiveness, both hyperesthesia and hypesthesia (Head zones), and tachycardia; and on questioning, one learns besides of headache and of unpleasant dreams at night. Many of the symptoms suggest the presence of the heart failure of chronic valvular disease. It will be seen, however, that this affection is strikingly different. It need scarcely be pointed out that the two conditions may coexist.

Naturally, not all these symptoms are necessarily present in the same patients, and besides the individual symptoms vary in the degree of severity. Indeed, the clinical picture varies within wide limits. In consequence, experience is required in order to recognize the cases, especially in the milder forms. Patients may, in fact, complain of a single symptom only. The most frequent of them, according to Hume, is pain in the chest, occurring in 768 out of 1,000 cases. Breathlessness comes next (675), then giddiness (403), palpitation (354), precordial tenderness (268), fainting with loss of consciousness (98), and fainting without loss of consciousness (25). As a matter of fact, it happens frequently that a single one of these complaints causes the soldier to report at sick call. But in addition to his complaint, if we suppose it to be precordial pain, he is likely to look worried, his face to look drawn, his brow contracted, his eyes unduly anxious, his hands and fingers ashake. Questioning may elicit the fact that he suffers from headache, bad dreams at night, pain of a fugitive nature elsewhere in the body, and an increasing disability to work. Examination discloses the presence of certain physical signs, to be discussed later. While the clinical picture that has just been drawn is common, the especial cause for sick report may be one of the other chief symptoms.

Indeed, any one of the chief complaints enumerated may appear alone and dominate the clinical picture. Experience must teach the large variety of combinations in which the chief symptoms occur. The peculiarities they present deserve detailed consideration.

The pain is usually located in the precordium or just above and to the left of it. Its position is not necessarily fixed; it may change from day to day. It may be felt on the right side of the chest, in the flanks or elsewhere. Sometimes, though, it is referred to the shoulders and arms. When the pain is in the chest, its character is usually sharp, sticking and fleeting, rarely constricting. It is probably not experienced at night and it does not keep the patient awake. Effort tends to bring it on, just as it tends to bring on the other symptoms. Associated with the pain, areas of skin hyperesthesia (Head zones) are found in from a quarter to one half of the cases. The intensity of this symptom varies. Patients may complain of it as due to the pressure of clothing. In other instances, its presence is elicited on examination. Pressure between the fingers of the pectoral, deltoid and sternomastoid muscles may elicit unilateral or bilateral tenderness. Boas[1] has in a similar manner found areas of hyperesthesia. The frequency with which this occurs is not known.

Breathlessness is likewise a common complaint and often the sole one. It interferes altogether with the normal performance of duty, such as a route march. It may be impossible objectively to detect the symptom, but not infrequently the distress is obvious. The rate of the respiration may be much elevated, especially as the result of effort. Frequencies of 60 and 80 per minute have been described. The relief from effort and the recumbent position are usually followed by the return of breathing to normal. But dyspnea, even when the degree is very striking, does not require the patient to be propped up in the way that heart disease does. Patients sleep quite flat or on one pillow, and the rate of breathing is normal. Cough and expectoration are not prominent.

There is, however, one type of case in which difficult breathing comes on, especially at night, in the form of attacks of nocturnal asthma. Such attacks are probably limited to those cases of the effort syndrome in which the patients have in addition been gassed. They are manifestations of gas poisoning rather than of the effort syndrome. They come on rather late (in from four to six weeks) after the gas attack. It is a form of respiratory distress that requires special mention under treatment.

---

[1] Boas: Personal communication to the author.

In connection with breathlessness are often combined the sensations of extreme fatigue or lassitude and giddiness. The sense of fatigue alone may be so great as to be incapacitating. Walking on a level for 100 yards may suffice to engage all the patient's effort. Carrying light equipment, or using a shovel or rake may be quite beyond his strength. Muscular tone may be low. The patient is then unable to resist the examiner's effort to extend the arm when he has previously been directed to hold it flexed. The muscular weakness may, indeed, be general.

Giddiness is a very common complaint. It is a type in which objects external to the patient apparently do not tend to circulate about him. It is expressed rather as a desire on his part to steady himself against the impulse to fall. Black spots and other abnormal visual phenomena, common in the vertigo of hypersensitive circulatory diseases or in chronic nephritis, are not prominent complaints.

Attacks of fainting occur in a moderate number of men. Sometimes consciousness is retained, but more often it is lost. Care must be taken in distinguishing this condition from true epilepsy.

Cardiac palpitation is a common symptom. It may accompany elevation of the pulse rate, but it need not do so. It may persist during rest.

Examination of the patient brings out a number of signs in addition to those to which the patient has attracted attention. Prominent among these are tremor, sweating and tachycardia. The tremor is coarse and is a shake rather than a tremor. It involves not only the fingers and hands but occasionally all the extremities and the head and the entire trunk as well. Patients who have it in a marked degree, and have the anxious facies as well, present a distressing picture. But the importance of the tremor, striking sign that it is, is easily exaggerated. Examples of it are widely distributed. It may occur in men who give no evidence of suffering from the effort syndrome. It is found, in fact, in great numbers of men who have never been away from a base port. On the other hand, it is entirely absent in equally large numbers of men who have served fairly long periods in the trenches and have sustained wounds. When it is associated with the effort syndrome, its prominence overshadows the picture; but in spite of that, it has not for the reasons given been found valuable as a guide in diagnosis or as an index of progress in treatment.

Profuse sweating is common, even when the weather forms no adequate reason for it. Sweat may stand on the face and drop from the axillae. There are other evidence of hyperactivity of the skin, such as the occurrence of wheals on stroking. The occurrence of Head zones, both of hyperesthesia and hypesthesia, has already been mentioned.

Of especial interest is the examination of the heart, to which most of the symptoms, such as pain, breathlessness, tachycardia, and fatigue, are naturally referred. The pulsation of the precordium is often striking, and may extend as a wavelike motion over two or three intercostal spaces. The thrust forward of the apex impulse may be especially forcible; in fact, it is often felt to be so. A thrill is not felt, but very frequently the impulse is not the simple, single thrust normally experienced, but rather is split, giving the impression of a major thrust split into a succession of ill defined minor parts. One is reminded of the thrill in presystole of mitral stenosis. But the thrill in mitral stenosis differs distinctly from this, especially in the matter of its timing. This thrill, due no doubt to overaction, occurs distinctly in systole, at the time of the first sound. A single sharp shock, synchronous with the second sound, is also often felt both at the apex and at the base. In size the heart is not enlarged. Indeed, measurement[2] made from teleroentgenograms shows that it tends to be smaller than normal rather than larger. An exact statement of size is, however, difficult to give. Normal size depends on the nature of the patient's activity. It is generally admitted that in the soldier on active field duty, the average size is usually greater by 2 cm. than was his heart before enlistment. Estimates of size should take this fact into consideration. The expected total transverse measurement may be given as between 11 and 13 cm. It is doubtful whether in the effort syndrome cases, when these facts are taken into account, enlargement occurs. The precautions already urged in estimating the size of the heart apply, of course, equally here. On auscultation, much difficulty has been experienced in distinguishing what one hears from the signs of mitral stenosis. The first sound is often unclean. As one might have expected on palpation, it has a serrated quality, the serrations being equal, confined within the limits of the first sound and replacing it. But it is precisely these serrations that cause confusion with the presystolic murmur of mitral stenosis. It need not be pointed out that serrations in the first sound are not the same as the crescendo murmur before that sound.[3] When the rate of the heart is elevated, as is often the case, the difficulty of accurate auscultation is naturally increased. Usually the second sound is not accentuated either at the apex or in the base areas. The absence of accentuation is a sign of value; for although it cannot be said always to be true that when the mitral stenosis is actually present, the second sound is accentuated, this, nevertheless, is generally the fact. The liability to confusion is emphasized because the error in diagnosis has frequently been made and has wrought harm not only to the service but also to diagnostic standards. Occasionally the diagnosis of mitral stenosis is made because in recent years students and physicians have been urged not to fail to make this diagnosis, even if the rumbling presystolic murmur is absent. They have been told that a snapping first sound suffices to establish the presence of the disease. The warning is proper, but insistence ought also to be laid on the fact that later an accentuated second sound should be looked for and found present. It is not contended that the diagnosis of mitral stenosis cannot or should not be made unless the characteristic murmur is present. In fact, the murmur is not always present. But insistence should also be laid on the fact that the diagnosis should be made after due attention has been given to the history of the patient and to exact auscultation. Anxiety to avoid one error has led many into making the other.

---

[2] Medical Research Committee, Special Report Series, No. 8.

[3] It is appreciated that insistance on the crescendo *character* is not quite proper, for, as Gerhardt has pointed out, the crescendo character of the murmur is *not a property of* its own, but is lent to it, because it terminates, when the P R time is normal, in a sharp first sound.

On occasion it is a difficult matter, even after all precautions have been taken, to be certain that a presystolic murmur is present. Various maneuvers have before now been recommended to make it evident, such as altering the posture of the patient, holding the breath, and undertaking exercise. Morison and Lewis[4] have recently hit on another method, which they say is effective in certain instances. They lay the patient in the recumbent posture and place the bell of the stethoscope at the site at which it is anticipated a presystolic murmur may be heard. The patient then inhales 3 minims of amyl nitrite. During the first ten or twenty beats, the only change is an acceleration in rate; during the second ten or twenty beats, the anticipated murmur may appear; during the third ten or twenty beats, the murmur usually disappears. The duration of the test is short. Auscultation must be practiced continuously throughout its performance.

The effort syndrome is not associated with a disturbance in the rhythm of the heart. Regularity, except for sinus arrhythmia, which is a normal phenomenon, is maintained. Although the affection does not involve a disordered action of the heart (D. A. H.), irregularities may naturally be found, as they are found accidentally in any large group in the community; but they are not a factor in the syndrome.

RANGE OF HEART BEAT

Pulse Rates	Per Cent.	
From 40 to 50	0.1	
From 50 to 60	0.5	
From 60 to 70	1.8	
From 70 to 80	8.5	
From 80 to 90	13.5	
From 90 to 100	22.4	46.2
From 100 to 110	23.8	
From 110 to 120	14.7	26.0
From 120 to 130	11.3	
From 130 to 140	1.4	
From 140 to 150	0.9	
From 150 to 160	0.1	

The rate of the heart beat is usually accelerated. The range, as shown by the accompanying table, is between 90 and 110 in 46.2 per cent., and between 110 and 130 in 26.0 per cent. of the cases, or between 90 and 130 in 72.2 per cent. of the cases. These figures are taken from Hume. There need be no elevation, as the table shows. It is, perhaps, important to point out that the rate tends to become unstable. In the same patient, it may on the same or on successive days fluctuate between wide limits. Sometimes, of course, stability at one or another level may be maintained. The fact of instability is mentioned especially because of the tendency to use cardiac rate in estimating prognosis.

ETIOLOGY

The significance of the affection we are considering has been the subject of a great deal of speculation. Certain suppositions in regard to its cause may be dismissed immediately; the importance of others must be weighed. First may be dismissed the thought that there are racial predispositions toward its occurrence. During the war, cases have been found in all the armies, Central as well as Allies. And among the Allies it is found among Hindustani, Scotch, Irish, Welsh, Canadians, Australians and New Zealanders. No race domiciled in the United States is free. It is found in nonsmoking peoples, like East Indians, as well as in smokers. It cannot, however, be said that smoking is harmless, so far as aggravating the condition is concerned. Investigation has not shown that it is dependent on a specific infecting organism, nor is it always associated with the occurrence of trench fever or rheumatism. Many who have had both diseases have not become subject to the effort syndrome. The liability, however, of men who have suffered from infectious diseases and especially from trench fever to suffer from the effort syndrome should not be overlooked. A point of especial importance relates to the tendency of trench fever to recur. Attacks are known to come on after afebrile intervals. These recurrences must be taken to indicate the possibility of residual infection. In view of the fact that on occasion tachycardia and its attendant symptoms are alone manifest, the infection itself may be regarded as involving the heart. It will be recalled that the occurrences exactly similar are encountered in convalescence from typhoid fever, dysentery and influenza. The relation of the effort syndrome to acidosis is too vague for us to attach importance to the few uncertain experiments that have been reported. By the method of respiratory analysis, Wilson and Levine[5] failed to find that a deviation from the normal exists.

Of more importance is the possibility of the disturbance of thyroid secretion. Symptoms associated with exophthalmic goiter are in some respects like those found in the effort syndrome. The symptoms in common are nervousness, tremor and tachycardia. In the effort syndrome, exophthalmos or thyroid enlargement is usually absent. There need be no diarrhea. Tachycardia may be absent. The tremor is really no tremor, but a shake, and it attains degrees of severity never seen in the most advanced cases of exophthalmic goiter. On the other hand, when tachycardia in exophthalmic goiter develops to as high a rate as is attained in the effort syndrome, there is usually a certain degree of dyspnea as well, and the size of the heart is definitely increased, whereas there is no reason for believing that this occurs in the effort syndrome. Between the conditions, a striking difference is observed at night. When tachycardia and dyspnea in exophthalmic goiter are sufficiently severe to attract attention, they persist, as a rule. In the effort syndrome, on the other hand, both disappear. The presence of small thyroid tumors or slight symmetrical enlargement of the gland can scarcely be taken as evidence in favor of hyperthyroidism. Such enlargements occur in large numbers of persons in certain sections of the United States, as elsewhere. They are not necessarily accompanied by symptoms either of developing exophthalmic goiter or of the effort syndrome.

The fact is appreciated that in the minor grades of both conditions the symptoms may be vaguely defined and might easily be confused. Investigations should be instituted with the view of developing specific methods of diagnosis in the early stages. Such studies should yield important results for diagnosis and consequently for treatment. In the later stages, when the cardinal symptoms of both are well established, no difficulty exists. For the present, reliance in diagnosis must be placed on the symptoms and signs already described.

A word should be said about those cases of the effort syndrome that occur after gassing. Confusion has occurred in relation to them. Many gassed patients have the symptoms of the effort syndrome; many, however, have not. But both groups develop the symptoms of nocturnal asthma, to which reference has already been made. They have been found to have polycythemia as well. Barcroft and Haldane and Meakins deserve credit for having called attention to this group of patients. Both symptoms, asthma and polycythemia, are properly ascribed to a late stage of gassing. They may, of course, occur in individuals who have also the symptoms of the effort syndrome. But it must be clearly understood that such patients are sufferers from two complaints, late gassing and the effort syndrome. The two are not necessarily associated.

[5] Wilson and Levine: Personal communication to the author.

RELATION TO WAR PSYCHONEUROSES

The most difficult part of the subject to discuss is its relation to the war psychoneuroses. In their pronounced forms, these naturally present no difficulty in diagnosis. Neither do the effort syndrome cases without psychoneurotic symptoms cause difficulty. But there are cases in large numbers that exhibit symptoms belonging to both groups. These cases present a twofold problem, one in classification or diagnosis, the other in therapy. The difficulty in diagnosis lies at the very root of the problem. There is no disposition to add new elements of confusion to the subject, but another attitude toward the subject must be suggested. It is a fact that many effort syndrome cases have not arisen de novo as the result of the war. The taking of proper histories brings out the fact that the beginning of the affection is of long standing. The complaints were initially too insignificant and too little insistent to require serious attention. During military service, however, the civil factors of safety fail to suffice for the individual's protection, the defect becomes prominent and the patient suffers. The important point is that the affection is of long standing but latent. It requires a stimulus, like the stress of war, to make the trouble patent. The stimulus becomes operative in a manner already habitual to the individual. The reaction is cardiovascular.

Those classed as psychoneurotics have a similar history. The stimulus that drives their latent defects into consciousness is the same. They differ in that their previous histories and their personal psychology predispose them to a different reaction. The manifestations of their affection lie in the domain of neuropsychiatry and require no detailed description here.

There is another group of more complex nature, the individuals in which react to the stimuli of war by more manifestations, and more varied ones, partly psychoneurotic, partly cardiovascular. In the same way, reactions may be found which are, for instance, gastro-intestinal or muscular. In all these varieties the stimuli furnished by the war may be similar. The reaction is a matter partly of chance, partly of predisposition.

TREATMENT

Lewis has offered a most important contribution to the methods for managing the malady, especially from the military point of view. For this purpose there was required a technic for sorting men in grades for service. He concluded that the proper way of sorting men for physical exertion was to try out the men by physical tests. It was an obvious conclusion. Lewis succeeded in doing this by a system of graded exercises. The system works admirably, as is seen by the fact that in a certain group after eleven months of service, the classification then made proved to be substantially correct. But the limitations under which work was done at the British Military Heart Hospital no doubt prevented the introduction of additions in treatment, which a consideration of the affection indicates are obviously desirable.

The variety of origin of the cases must be remembered, in arranging for their management. Some of the patients are convalescents from acute infections, especially trench fever, bronchitis and pneumonia. The management of convalescence after these infections must be designed to safeguard patients from damage dependent on the relighting of their infection. Relapse after trench fever is known to occur with moderate frequency and should be promptly recognized. When it occurs, it is thought to depend on an involvement of the heart muscle. In such circumstances, physical exertion is naturally not indicated. Other cases are of men who have been gassed. Others have been of long standing and existed before the war. Still others have obviously shown no predisposition to the affection before the war. In any case, the principles of treatment are the same. The general rules of hygiene must, of course, be observed. The men should be made to understand that they are not ill. They should not, therefore, be collected in hospitals. In hospitals, moreover, the constant contact with disease and the suggestions arising from this contact are undesirable but unavoidable. The proper environment for them is supplied by camps under suitable medicomilitary discipline. It is necessary to insist on the medical rather than the military side of the management, although there should be no underestimation of the importance of military discipline. The discipline must be rigid, but appropriate to the degree of disability of the men. Occupation must be found for them, and especially occupation for their minds. It is an error to permit them to rely on their own resources alone. When this side of their treatment is neglected, they speedily become bored, listless and undisciplined. They begin to brood on their disability until their mental background, deranged in the first instance, is worse in the last state than in the first.

In practice, attention should be given to the minor sources of infection, such as infection of the accessory nasal sinuses, the teeth, tonsils and ears. These infections should be removed.

Physical exercises should be arranged for the patients. Three methods are suggested: drill, farm or garden work, and games. The drill should be graded according to the ability of the patient to perform it. It may be varied both as to severity and as to duration. At best, however, drill may occupy only a small portion of the day and may be supplemented by route marches. Farm and garden work may, of course, also be adapted to the capacity for endurance of the individual for work of this kind. It has the advantage of variety and may be performed without that nervous strain which the sharp orders given at drill by the drill sergeant necessarily entails. The introduction of games invites men unconsciously to undertake a great deal of physical exercise without that feeling of compulsion which attaches to the other forms of exercise. Their number may be added to and varied by the imagination of the medical officers. To the forms of exercise may be added, if the facilities are presented, training in occupations of use in the Army. Advice as to these must be sought from time to time. Men are constantly wanted as stenographers, typists, telegraphers, mechanics in gun, automobile or wagon repairing, railway attendants, and hospital orderlies.

The mention of disturbance in mental background leads naturally to a consideration of the share neuropsychiatrists must have in the treatment of certain of the cases. In point of fact, even when the symptoms are predominantly cardiovascular, the neuropathic side of the picture is frequently prominently developed. The importance of this side of the therapeutic problem, if neglected, may actually increase during the period of treatment. The requirements for aid in this direction vary. The difficulties may be mimetic or inherent in the individuals. And again some men, reticent by nature, in the attempt to suppress interest in their symptoms are troubled by dreams of an uncomfortable kind.

CONCLUSION

It has been my purpose to indicate the general features of this affection of soldiers. The attempt has been made to show how involved the syndrome is, and how it touches intimately other domains in medicine aside from the cardiovascular. Its etiology cannot now be conscientiously indicated, nor its exact relation to the numerous processes involved, which are familiar and the connections of which with this entity immediately suggest themselves. It is impossible to lay down rigid laws for treatment; that may be done only when the exact pathologic physiology is established. But suggestions are made for dealing with the problem not only for the purpose of sorting, which is purely military, but also for the purpose of therapeutic improvement, which is the aim of clinical medicine.

ISOLATION OF INFLUENZA BACILLUS FROM THE BLOOD

REPORT OF TWO CASES

J. S. FLEMING, M.D. (Memphis, Tenn.)
First Lieutenant, M. C., U. S. Army; Chief of the Laboratory Service, Base Hospital No. 106, A. E. F.
FRANCE

Case 1.—*Clinical History.*—The patient was admitted to the hospital, Sept. 27, 1918, two days after the onset of influenza with headache and aching all over. The patient had a cough, but no bloody sputum. The bowels had not moved for two days. The throat was very red. There were a few sibilant râles in the right axilla and anteriorly.

September 29, the temperature was elevated, the pulse rapid, and the entire chest full of large, moist râles. The condition was diagnosed as bronchopneumonia.

September 30, the patient was very much prostrated, the skin dry and harsh. Respiration was markedly increased with almost complete absence of breath sounds over the right middle and lower lobes. There was increased voice fremitus. There was flatness on percussion. There were no râles. The diagnosis was lobar pneumonia.

October 1, the pulse was 124 and rather weak; there was marked elevation of temperature. The right base posteriorly seemed slightly dull and changed in voice sounds. There was no bronchial breathing. The neck was not stiff. The diagnosis was changed to bronchopneumonia, and the subsequent trend of events proved this to be correct.

October 2, the face was flushed, the ears cyanotic, the tongue coated, the pharynx inflamed, and there was dulness at the left base. There were areas of bronchial breathing and also left axillary râles. There were areas of dulness over the right base posteriorly.

October 3, the patient was somewhat cyanotic. Breathing was rapid, and there was impaired resonance over the entire right side, especially the base. There were many râles over both bases, especially the left. The patient's condition was very serious.

October 4, the patient was very cyanotic, the pulse weak and rapid, and the condition serious. The right base posteriorly was dull on percussion, with crepitant râles and distressed breathing.

October 5, there were dulness and râles over both bases. The patient was cyanotic. The pulse was weak.

October 7, both lower lobes showed scattered areas of bronchovesicular breathing.

October 8, the patient appeared slightly improved. There were still many râles throughout the chest. Voice, especially at the base, was very weak. The heart was of fair quality. There was no rigidity of the neck. The pupils were equal. Later the pulse was rapid, the respiration labored, and the patient very weak and cyanotic. Still later, the patient was comatose, very weak and cyanotic. Breathing was rapid and shallow. The pulse was weak. Finally, the patient was profoundly toxic, and too ill to examine.

October 9, the patient died at 2:05 a. m.

Laboratory Diagnosis.—A blood culture was taken, October 9. Ten c.c. of blood were introduced into a bottle containing 150 c.c. of a 1 per cent. glucose broth. The reaction was 0.3 plus. This was incubated at 37 C. Transfers from a twenty-four hour culture were negative. Transfers from a forty-eight hour culture showed a very fine, sparse growth practically unnoticeable unless examined with a hand lens. Morphologically these colonies resembled the influenza bacillus. Smear showed minute gram-negative diplobacilli with all the general appearances of influenza bacilli. Five-tenths c.c. of broth from the seventy-two hour culture was then injected into the peritoneal cavity of a white mouse. The following morning the peritoneal exudate showed large numbers of characteristic gram-negative bacilli, which on transfer gave a typical growth on blood agar plates but failed to grow on blood-free mediums. A mouse died in forty-eight hours. The same organisms were still present in the peritoneal cavity. The heart's blood failed to show growth.

Case 2.—*Clinical History.*—The patient, admitted to the hospital, Sept. 26, 1918, had been taken ill the day before with cough, headache, backache and pains all over the body, and fever. He had fainted twice.

September 30, there was dulness in the right lower lobe anteriorly on percussion. There were many small, moist râles. No change in voice or respiration was noted. Fremitus was present. The condition was diagnosed as possibly bronchopneumonia.

October 1, there was dulness over the entire right lower lobe. There were many small, moist râles on coughing, and musical, moist râles over the entire right lower lobe. There was fremitus in both lower lobes. The condition was slightly worse than on the preceding day.

October 5, the patient was in a profuse perspiration. There was dulness in the left upper lobe and in the right lower lobe, with signs of consolidation. There were a few moist râles in the other lobes.

October 8, the patient's general condition was somewhat improved. In the afternoon there were some signs of pleurisy.

October 9, the temperature was elevated. The patient still complained of pain in both lower parts of the chest. There was no change in percussion. Friction rub and dry râles were noted especially in the left upper lobe. There was no cyanosis. Cerebrospinal symptoms were absent. The reflexes were normal.

October 10, in the morning, there was no dulness nor change in voice or breathing. There were dry, musical, and large, moist râles throughout both sides of the chest. There were no signs of fluid. In the afternoon the temperature, pulse and respiration were higher. There was no endocardial trouble.

October 11, the patient's condition was not so good. There were general mixed râles throughout the chest.

October 12, there were dry, moist and musical râles of all sizes throughout both sides of the chest, especially in the lower lobes. There were no areas of consolidation. The general condition was very good.

I was unable to complete this history.

Laboratory Diagnosis.—Blood culture was taken, October 10. The same procedure was followed as in the previous case, with practically identical results except that the mouse had not died up to the date of my departure.

COMMENT

These two blood cultures were not taken with any hope of finding the influenza bacillus, but were secured from severely ill patients with the probability of finding the more ordinary bacteria usually associated with respiratory infections. Reasoning on that basis, the logical assumption would be that it is possible to isolate the influenza bacillus from the blood in a sufficient number of clinically influenza cases to prove undoubtedly the etiology of the prevailing epidemic of so-called "Spanish influenza."

Owing to my transfer from Camp Jackson, I am unable to undertake this, but the foregoing short and incomplete report may be interesting to others.

On approximately 100 throat cultures taken for meningitis, the number of plates showing the presence (macroscopically) of influenza colonies has been striking, especially to me after having examined thousands of plates last winter, when its presence did not seem common.

PANDEMIC "INFLUENZA" AND SECONDARY PNEUMONIA AT CAMP FREMONT, CALIF.

WALTER V. BREM, M.D. (Los Angeles)
Major, M. C., U. S. Army; Chief of the Medical Service

GEORGE E. BOLLING (Brockton, Mass.)
Captain, S. C., U. S. Army; Chief of the Laboratory

AND

ERVIN J. CASPER, M.D. (San Francisco)
First Lieutenant, M. C., U. S. Army

CAMP FREMONT, PALO ALTO, CALIF.

The expected storm of the prevailing pandemic infection broke suddenly on the Eighth Division, U. S. Army, Camp Fremont, Calif., Oct. 8, 1918, and during the next six weeks, 2,418 patients suffering from respiratory diseases were admitted to the base hospital. In addition, many soldiers having more or less mild infections were cared for in the various camp infirmaries in order to avoid overcrowding in the base hospital. Altogether there were, at a conservative estimate, 3,000 cases.

Pneumonia was diagnosed in 408 cases, an incidence of nearly 14 per cent. We know now, however, that there were many cases of pneumonia that were diagnosed as bronchitis, and that the true incidence of pneumonia was greater than that indicated.

Of the 408 patients with pneumonia diagnosed, 147 died, a mortality of 36 per cent. for the pneumonia series and about 5 per cent. for the epidemic. No deaths occurred without a complication of either lobar pneumonia or bronchopneumonia, an observation in accord with that of Christian.[1]

CLINICAL FEATURES

As one reflects on the clinical features of the epidemic, one finds oneself impressed by certain striking and characteristic phenomena:

1. *Hemorrhage.*—Epistaxis was a common feature throughout. At first we looked on it as merely an incidental occurrence, as in typhoid fever, and not as possessing special significance. Instances of epistaxis multiplied, however, and often blood was seen to gush from a patient's nose and mouth. When pneumonia appeared, the patients often spat quantities of almost pure blood. Female patients, of whom there were altogether about 100, had a hemorrhagic vaginal discharge, which at first was thought to be coincident menstruation, but later was interpreted as hemorrhage from the uterine mucosa. Finally, the extraordinary hemorrhagic picture seen at necropsy, together with the constant leukopenia in the initial stages, completed the evidence that led us to believe that an important feature of the disease is some kind of blood dyscrasia, which is of grave significance and suggestive of purpura hemorrhagica. In a few patients, large purpuric areas developed in the skin.

We feel that this condition is due to a depressant influence exerted by the initial infection on the bone marrow, and that it is closely related to the next extraordinary feature of the disease.

2. *Leukopenia.*—In the influenzal stage, leukopenia was practically always found, and at first it appeared to be a feature also of the pneumonic stage. Indeed, one saw many full blown cases of apparently lobar pneumonia with a leukocyte count of less than 5,000; there were five cases with a count of 3,000 or less. Smears from the lungs of some of the fatal cases showed innumerable diplococci with the large pneumococcus type of capsule, and the cultures were positive for pneumococci.

But other pneumonia patients with early leukopenia recovered, and when subsequent counts were made, it was found that in each case there was a gradual rise to from 10,000 to 24,000 leukocytes.

The conviction gradually developed, therefore, that the influence of the initial infection was a depressant one on the bone marrow resulting in leukopenia, while, on the contrary, the pneumonic infection tended to stimulate, as usual, the production of leukocytes, which gradually increased in number in the blood stream as the depressant influence waned. The leukocyte counts, from which the foregoing conclusion was drawn, are given in Table 1.

TABLE 1.—LEUKOCYTE COUNTS IN ONE HUNDRED AND FORTY-EIGHT CASES OF PNEUMONIA

Leukocyte *Counts*		2,000-3,000	3,000-5,000	5,000-7,000	7,000-10,000	10,000	Average Count
Fifty-Six Fatal Pneumonia Cases:							
First counts	56	3	26	8	12	7	6,320
Second counts	13	..	6	1	5	1	6,730
Third counts	1	..	..	1	..	..	5,800
Ninety-Two Nonfatal Pneumonia Cases:							
First counts	92	2	18	34	14	24	8,300
Second counts	30	..	7	8	5	10	9,080
Third counts	11	..	..	1	2	8	12,500
Fourth counts	8	..	..	..	1	7	15,000
Total counts	211	5	67	52	38	48	

Average leukocyte count in 86 influenza cases, 6,000.
Average first count in 148 pneumonia cases, 6,800.

3. *Types of Pneumonia.*—Two characteristic types of pneumonia were differentiated.

(*a*) Lobar Pneumonia Type: The first, and most common type, was that which when well developed gave the physical signs of lobar pneumonia. The onset usually occurred when defervescence of the symptoms of the initial infection was almost or quite complete, about the third or fourth day. It was ushered in frequently by a chill, a sharp rise of temperature, a localized explosive shower of fine râles usually about the angle of the scapula and more frequently on the left side, and bloody sputum, amounting often to marked hemoptysis. A few roentgenographic examinations at this stage showed shadows indicating that already consolidation was beginning. Occasionally the milder of these cases cleared up quickly without further signs of pneumonia developing, but most of them proceeded to a stage of definite signs of consolidation of one or more lobes.

---

[1] Christian, H. A.: Incorrectness of the Diagnosis of Death from Influenza, The Journal A. M. A., Nov. 9, 1918, p. 1565.

The temperature curve was irregular, frequently not rising as high as from the initial infection, and usually ending by lysis, the mean duration of the pneumonia fever being about seven days. The pulse rate was slow in proportion to the fever, and the blood pressure was low, the systolic pressure frequently being 100, and the diastolic pressure from 40 to 50. The pulse pressure was good, and there were no signs of cardiac insufficiency except in the fatal cases after the onset of respiratory insufficiency and shortly before the end. The danger never appeared to arise from the effect of the infection on the cardiovascular mechanism.

The respiratory rate, likewise, was slow in proportion to the fever until the toxemia became marked, when the respirations became accelerated and the respiratory abdominal excursions limited. The chief toxic effect of the infection seemed to be exerted on the respiratory mechanism, failure of which, due to excessive toxemia and to the mechanical effect of extensive consolidations and hemorrhagic edema of the lungs, caused the death of patients.

We do not know whether this type is a true lobar pneumonia or a massive bronchopneumonia due to the fusion of small areas, but we believe that it is a lobar pneumonia with the pathologic picture modified by the hemorrhagic exudate and the paucity of leukocytes.

Our reasons for this opinion are:

(1) The onset of the pneumonia was sudden, usually with a chill, frequently after the temperature of the initial infection had fallen almost or quite to normal, and there was no intermediate stage of the physical signs of bronchitis.

(2) The mean duration of the pneumonia fever was about seven days.

(3) The lungs at necropsy showed massive, air-free consolidations without any definite lobular pattern; no pus could be expressed from the bronchi; the bronchial mucosa did not show a purulent exudate or any special inflammatory thickening or change other than marked congestion, and there was practically no fibrin in the exudate. These findings were in marked contrast to the true bronchopneumonia type to be described presently.

(4) The avenue of infection of the lungs did not appear, therefore, to be by extension along the bronchial mucosa, but by way of the blood stream, as is probably the case in ordinary lobar pneumonia.

(5) The bacteriologic findings were different from those of the bronchopneumonia type.

(*b*) *Bronchopneumonic Type:* The second type was that of true bronchopneumonia. The onset was not clearly defined, the course being continuous with that of the initial infection; the temperature curve was irregular; the sputum was not bloody, but purulent ("nummular"); physical signs of diffuse bronchitis were usually present. Fatal cases sometimes showed a low or even normal temperature with cyanosis and marked "air hunger." The patient belonging to this group had a normal temperature, good pulse, no sputum, and no râles in his chest. The percussion note over the lungs was hyperresonant, the breath sounds distant and scarcely audible; there was marked dyspnea and cyanosis. The diagnosis was not suspected until necropsy disclosed the real condition. The bronchi were full of pus; and little nodules, bronchopneumonic consolidations, were scattered uniformly throughout the lungs. Death appeared to be due to actual asphyxiation.

Five patients with this type of pneumonia developed a puzzling subcutaneous emphysema, which, in the most marked case, extended from the forehead to Poupart's ligament in front and the buttocks behind. The postmortem examination demonstrated in two cases that emphysematous air cells at the root of the right lung had ruptured into the loose mediastinal tissues, and that the air had progressed upward to the neck, and infiltrated the subcutaneous tissues. Cultures from the subcutaneous tissue for anaerobic organisms were negative.

The clinical features of this type, and also the pathologic features, to be described, indicated that it was due to a direct extension of the inflammation down the bronchial mucosa. *B. influenzae* was found in cultures from the pus droplets of the small consolidated areas in the three cases carefully studied bacteriologically at necropsy—twice in pure culture, one with *M. catarrhalis.*

The leukocyte counts in this group are few. In two fatal cases there were 7,600 and 6,000 leukocytes, respectively. In the second case the count rose to 16,400 before death. *B. influenzae* was present in pure culture in the lungs in both cases.

We cannot estimate the relative percentages of the two types of pneumonia, for they were differentiated but late in the epidemic, and the clinical records do not enable one to separate them. It is certain, however, that the first type is far the more common, but the second type is by no means infrequent.

4. *Other Clinical Features of Interest.*—These may be thus grouped together:

(*a*) Frequency of pneumonic involvement of the left lower lobe.

(*b*) Irregularity of the pneumonia temperature and infrequency of termination by crisis.

(*c*) Frequency and grave significance of cyanosis, which often seemed to appear before the onset of respiratory insufficiency.

(*d*) Relatively slow pulse and respiratory rates associated with high temperatures.

(*e*) Low systolic and diastolic blood pressure and good pulse pressure.

(*f*) Relative infrequency of otitis media.

(*g*) Infrequency of empyema and other complications of pneumonia (in only one pneumonia case did empyema develop).

(*h*) High pneumonia mortality rate.

PATHOLOGIC FEATURES

Deaths were always due to pneumonia. In thirty postmortem examinations, lobar pneumonia was diagnosed twenty-five times, bronchopneumonia, five times.

The two types presented striking differences at the postmortem examination:

1. *Lobar Pneumonia Type.*—Frothy, bloody serum poured from the nose and mouth when the body was moved or the head lowered. On section of the skin, dark blood oozed from the cut vessels. The pleural cavities always contained a quantity of serosanguineous fluid, but the pleurae did not show the fibrinopurulent exudate commonly found in lobar pneumonia.

The lungs were extensively involved, there being practically always large areas of consolidation in several lobes; hemorrhages under the pleurae were frequently seen; the lungs were dark red and irregularly mottled, very moist and bloody, the cut surface smooth and velvety; the consolidated areas contained no air, and no pus could be expressed from the bronchi. The early condition was that of acute hemorrhagic edema.

The peribronchial lymphatic glands were very large, dark red, congested, soft and friable.

The heart muscle was dark red, relaxed and flabby, offering a strong contrast to the firm, contracted left ventricle nearly always present postmortem in bodies of patients dying from lobar pneumonia; the heart's blood was fluid and dark, there being only small, flimsy, postmortem clots and no "chicken fat" clots. The abdominal viscera showed marked congestion, the glomeruli of the kidneys standing out distinctly.

Microscopically, the alveoli of the lungs were full of red blood cells in the portions recently involved; in the older portions polymorphonuclear leukocytes became more or less prominent in the exudate; no fibrin was seen; the bronchi were not plugged with pus; the blood vessels were engorged.

2. *Bronchopneumonia Type.*—The tissues of the bodies were dry; there was no "frothing at the mouth"; no blood oozed from small cut vessels; the pleural cavities contained no fluid, but there were patchy areas of fibrinopurulent exudate with recent, easily separated pleural adhesions.

The lungs were very pale and extremely voluminous, and did not collapse when the chest was opened. Emphysematous bullous-like areas beneath and elevating the pleurae were common; these had transparent bubble-thin walls and were divided into numerous compartments by the walls of the dilated air cells. Pus streamed from the trachea when the lungs were removed. Small areas, from 2 to 5 mm. in diameter, of consolidated tissue were scattered uniformly throughout the lungs, and these little areas felt like disseminated conglomerate tubercles. On section, the lungs were dry, the solid areas were gray and granular in appearance, and a drop of pus could be expressed from the center of each. In one case, about half of the right upper lobe was consolidated; it had a mottled gray, granular appearance, and there were numerous points where droplets of pus could be expressed, the large area of consolidation being evidently formed by the confluence of smaller areas of bronchopneumonia.

The peribronchial lymphatic glands were very large, the cut surface gray and granulated. They were soft and friable.

The heart showed nothing remarkable, nor did the abdominal viscera. In one case the spleen was quite large and the malpighian bodies stood out distinctly, and the liver and kidneys showed cloudy swelling. In two necropsies the mediastinal and subcutaneous tissues showed marked emphysema due to the rupture of dilated thin walled air cells on the anterior surface of the root of the right lung into the loose mediastinal tissue.

Microscopically, the consolidated areas of the lungs showed a bronchiole full of pus cells and the surrounding alveoli packed with pus cells and desquamated epithelium, and there was considerable fibrin formation. The air cells of the adjacent uninvolved lung were dilated and the walls were thin; the vessels were *not* engorged.

BACTERIOLOGIC FEATURES

Cultures from the nasopharynx were made from every patient admitted to two of the wards; 148 patients were examined, and *B. influenzae* was isolated from thirty-seven patients, or 25 per cent. Ten of these patients, or 27 per cent., developed pneumonia. The findings in this series are given in Table 2, which shows also the number of patients that developed pneumonia.

TABLE 2.—BACTERIOLOGIC FINDINGS IN CULTURES FROM THE NASOPHARYNX OF ONE HUNDRED AND FORTY-EIGHT SUCCESSIVE EPIDEMIC CASES

	Number	Per Cent.	Developed Pneumonia	Per Cent.
B. influenzae with other organisms	37	25	10	28
Pneumococcus alone	67	45	15	22
Pneumococcus and streptococcus	22	15	4	18
Pneumococcus, streptococcus and M. catarrhalis	5	3	2	40
Total pneumococci	94	63	21	22
Total streptococci	27	18	6	22
M. catarrhalis alone	16	11	2	12.5
Total M. catarrhalis	21	14	4	19

Similar cultures from the nasopharynx were made in 537 cases. These were usually selected severe cases of respiratory infections. The results are given in Table 3, and other bacteriologic findings in tables that follow.

TABLE 3.—BACTERIOLOGIC FINDINGS IN CULTURES FROM THE NASOPHARYNX OF FIVE HUNDRED AND THIRTY-SEVEN SELECTED SEVERE EPIDEMIC CASES

	Number	Per Cent.
B. influenzae	259*	46
Pneumococci	149	28
Streptococci, all kinds	160	30
Staphylococci, all kinds	64	12
M. catarrhalis	62	11.5

* B. influenzae was usually associated with other organisms. There were a few pure cultures.

TABLE 4.—BACTERIOLOGIC FINDINGS IN CULTURES FROM THE NASOPHARYNX OR SPUTUM OF ONE HUNDRED AND FIFTY-EIGHT PNEUMONIA CASES

	Number	Per Cent.
B. influenzae	58*	38
Pneumococci	64	40.5
Streptococci, all kinds	46	29
Staphylococci, all kinds	21	13
M. catarrhalis	11	7

* B. influenzae was practically always associated with other organisms.

In three cases of the bronchopneumonia type, smears from the pus droplets expressed from the small consolidated areas in the lungs showed innumerable small gram-negative bacilli, and *B. influenzae* was cultivated, twice in pure culture and once with *Micro-*

coccus catarrhalis. Cultures from the heart's blood were negative in all three cases.

Pneumococci from all cultures were typed thirty-eight times.

For cultures of *B. influenzae* during the first part of the epidemic, the surface of ordinary blood agar plates was inoculated. Later the blood agar was heated to 70 C. for fifteen minutes, poured in plates, and the surface inoculated. The latter method proved much more effectual for the isolation of *B. influenzae.*

ETIOLOGY

The results of the bacteriologic examinations are disappointing and their value small in proportion to the amount of work entailed.

B. influenzae was a common organism during the epidemic, and was the one encountered most frequently in the group of selected severe respiratory infections. It was less frequently found than the pneumococcus in the series of 148 consecutive cases, and it was isolated only three times in the postmortem cultures from the lungs and three times from the heart's blood in twenty lobar pneumonia cases, twice with the pneumococcus and once with *Streptococcus viridans.* It was present, however, in cultures from the lungs in all of three fatal cases of bronchopneumonia, twice in pure culture and once with *Micrococcus catarrhalis.*

In view of the fact that *B. influenzae* is rather an uncommon organism in most epidemics of infections of the upper respiratory tract, its relative frequency in this epidemic may be of some etiologic significance. Otherwise there is no evidence that it is more than an incidental or secondary invader. Certain clinical phenomena point to the latter view, and to the fact that the organism initiating the epidemic is unknown.

The argument based on the clinical phenomena referred to is:

1. The initial infection, that is, the epidemic disease, apparently caused the hemorrhagic phenomena and the leukopenia.
2. In the purest and most intense *B. influenzae* infections (that is, in the three bronchopneumonia cases in which *B. influenzae* in great numbers was found in the pus filling the bronchial tree), there were no hemorrhagic manifestations, and two leukocyte counts in one of the cases showed a rise from 6,800 to 16,400.
3. Therefore, it seems improbable that *B. influenzae* was the organism initiating the epidemic.

It may be objected that there is no proof that the initial infection caused the hemorrhagic phenomena, which might have been caused by a secondary invader with special characteristics, for example, pneumococcus Type IV. This objection is difficult to meet, especially in view of the fact that fatal cases of the lobar pneumonia type showed hemorrhagic phenomena of extreme degree and a persistent leukopenia. However, many uncomplicated cases of the epidemic disease manifested hemorrhagic phenomena and usually leukopenia, while in nonfatal secondary pneumonia cases both the hemorrhagic phenomena and the leukopenia disappeared during the course of the pneumonia. As we have stated elsewhere, we believe that the hemorrhages and the leukopenia were both due to a depressant action of the initial infection on the bone marrow, and that the secondary pneumonia infection tends to reactivate the bone marrow, which responds as the primary influence wanes. We believe, further, that in fatal cases the depressed bone marrow cannot react to the secondary stimulus, and hemorrhages and leukopenia persist.

From the evidence at hand, we feel justified, therefore, in adopting the following working hypothesis:

(*a*) The organism of the initial infection of the epidemic is unknown. It seems probable that it is an ultramicroscopic filtrable virus.

(*b*) Important features of the initial infection are hemorrhagic phenomena and leukopenia, indicating depressed activity of the bone marrow. Microscopic studies of the bone marrow and studies of the blood with reference to the platelets and the elements of coagulation are indicated.

(*c*) The primary infection causes lowered resistance to certain secondary organisms.

(*d*) The lobar pneumonia type of the secondary pneumonias is caused by a number of organisms, chief of which are pneumococci, *Streptococcus hemolyticus* and *Streptococcus viridans.* Pneumococci, Type IV, predominate.

(*e*) The bronchopneumonia type of the secondary pneumonia is caused by *B. influenzae.*

SPECIAL BLOOD EXAMINATIONS

Coagulation Tests.—An attempt was made to determine whether or not some element of coagulation was lacking in the blood. Two methods were used.

1. The coagulation time of the blood of fifteen patients was determined by the following technic: A syringe was thoroughly cleaned and sterilized, and the walls were moistened with physiologic sodium chlorid solution, enough being left to fill the needle so as to prevent the introduction of tissue juices. The needle was then introduced into a vein, an attempt being made to plunge it immediately into the vein so as to avoid

injuring tissues. Four c.c. of blood were aspirated and expelled into a thoroughly cleaned and dried test tube, 20 mm. in diameter. The blood was allowed to coagulate until the clot held intact to the bottom, when the tube was inverted. The time required for this was taken as the criterion of the coagulation time. The results are given in Table 8.

TABLE 8.—COAGULATION TIME WITH FRESH BLOOD AND 20 MM. TEST TUBES

	Number of Cases	Coagulation Time, Minutes
Normal controls	4	From 12 to 18
Hemorrhagic cases	3	6½ to 10
Hemorrhagic cases	11	11 to 15½
Hemorrhagic cases	1	22

The variations of the coagulation time were within the limits of accuracy of the test, and showed no definite deviations from normal.

2. A second series of eleven tests was made by oxalating the blood, making a total strength of 0.1 per cent. sodium oxalate, separating the plasma and adding increasing quantities of calcium chlorid, 0.5 per cent. Five drops of plasma were placed in each of three small tubes, and 1, 2 and 3 drops, respectively, of the calcium chlorid solution were added. The tube in which coagulation occurred first was taken as the one indicating the coagulation time.

TABLE 9.—COAGULATION TIME WITH OXALATED PLASMA AND CALCIUM CHLORID *

	Number of Cases	Coagulation Time, Minutes
Normal controls	3	From 7 to 12
Hemorrhagic cases	2	Under 7
Hemorrhagic cases	4	7 to 12
Hemorrhagic cases	3	12½ to 16
Hemorrhagic cases	1	17
Hemorrhagic cases	1	5½ hours

* Simon, C. E.: A Manual of Clinical Diagnosis, Philadelphia, Lea & Febiger, 1918, p. 105.

Four of the foregoing tests showed apparently a slight increase of coagulation time, and one a marked increase, the plasma requiring five and one-half hours to coagulate. A second test of this blood, made six hours after the administration intravenously of coagulen (to be discussed later) showed a coagulation time of only sixteen minutes.

The first method of testing coagulation time requires extreme care, for there are many influences tending to error that must be controlled. These influences all tend to shorten the coagulation time. Therefore, the absence of delayed coagulation in the series is not conclusive proof that some element of coagulation is not deficient.

The second method is less subject to technical errors, and the results are more dependable. The results of the tests in this series, however, are not sufficiently definite for conclusions to be drawn. The single test showing a markedly prolonged coagulation time, in the absence of other corroborative tests, must be looked on with the suspicion that the delay was due to some error in technic.

Bleeding Time.—A clean puncture of the ear was made, and the drop of blood was blotted up every fifteen seconds with filter paper until the paper was no longer stained. The time required is the "bleeding time" (Duke). The few tests that we made showed bleeding times within normal limits—from one and one-half to three minutes. A prolongation of bleeding time, according to Duke, is due to platelet deficiency, the number being insufficient to block the ends of the bleeding vessels. There was no evidence, therefore, from these tests that a deficiency of blood platelets existed. No platelet counts were made, but examination of carefully prepared cover-glass preparations of blood showed no apparent decrease of platelets.

Summary.—Clinical phenomena indicate that an important and grave feature of the epidemic disease is a blood dyscrasia manifested by hemorrhages and leukopenia. It is thought to be due to a depressant influence exerted by the initial infection on the bone marrow. Our incomplete laboratory examinations have not indicated clearly the nature of the blood dyscrasia, if there be one.

TREATMENT

Nonspecific.—Patients suffering from the upper respiratory infections received only the usual care of rest in bed, abundant food, cathartics and palliatives, such as acetylsalicylic acid. Great care was taken during convalescence to avoid exposure and overexertion, which, we believed, might be predisposing, etiologic factors of pneumonia.

The pneumonia patients were treated from the point of view of husbanding the defensive resources of the patient in order to gain time for the development of the offensive forces of immunity. Therefore, considering the fact that the work of the heart and respiratory mechanism is already increased above normal in pneumonia, stimulants were avoided, and an effort was made to keep the patients as nearly as possible at rest. Morphin was used freely to allay restlessness, pain and coughing and in an effort to reduce the respiratory rate and to increase the abdominal respiratory excursions, thereby to prevent fatigue of the respiratory center and to increase the efficiency of each respiratory effort. We felt safe in any given case as long as the abdominal respiratory movements remained good. The heart appeared to be affected relatively little by the infection, and the pulse usually continued good after respiratory insufficiency had set in. Oxygen was given for periods of five minutes with twenty-minute intervals to patients with respiratory insufficiency and cyanosis. It seemed to give temporary relief to some patients, but there was no evidence that it affected the final outcome. As a last resort, camphorated oil and caffein were given hypodermically as stimulants in a vain effort to "tide over" a critical period. Digitalis was not used. During the first half of the epidemic, whisky, one-half ounce, and strychnin, one-fortieth grain by mouth, were given alternately every two hours. These doses did not appear to have any effect on the patients, and it is our impression that the patients in this series did no better or worse than those of the later series, nor was there any significant difference in the mortality of the two series. Hydrotherapy was used externally and internally to combat the fever and toxemia.

In our plan of symptomatic treatment we find that we are in complete accordance with Strouse and Bloch.[2]

In regard to the use of opiates, one of us (Brem) has studied the effect on the respirations in pneumonia of a combination of heroin, one-twelfth grain, and codein, one-fourth grain, given hypdermically, and he has found it preferable to morphin for the prevention of respiratory fatigue. Heroin and codein seem to have a synergistic action, and they often lessen markedly the respiratory rate while definitely increasing the respiratory excursions. They should be given every four hours for a respiratory rate of 36 or greater, a rate of 40 per minute having been found to be approximately the danger line.

---

[2] Strouse, Solomon, and Bloch, Leon: Notes on the Present Epidemic of Respiratory Disease, The Journal A. M. A., Nov. 9, 1918, p. 1568.

Their effect is slight when the respiratory rate approaches 50 per minute. Pneumonia patients tolerate well large amounts of opiates, and the only contraindications are tympanites and a failure of the respirations to increase in depth while lessening in rate. The latter contingency should be judged by the excursion of the abdominal respiratory movements.

In two cases of the bronchopneumonia type, epinephrin and atropin were given to dilate the bronchi, and the head was lowered to promote drainage. The treatment was ineffectual, and both patients died.

Specific Treatment.—Polyvalent antipneumococcus serum was given in four unselected cases early in the course of pneumonia. Two of these patients made rather rapid recoveries, one ran a moderately severe course but recovered, and one died. This did not seem to be a deviation from the natural course of the disease uninfluenced by treatment, and since we did not consider the treatment immunologically hopeful we did not continue it.

Serum from five convalescent patients was pooled and 35 c.c. were given to each of five selected dangerously ill patients, all of whom were spitting blood. Though the blood spitting practically ceased in four cases and decreased in the fifth, all five patients died. This series does not furnish evidence against the value of convalescent serum, for only one comparatively small dose was administered to each patient, and at that time all of the five patients were extremely ill. We should have pursued investigations along this line but for other considerations, which will be discussed presently.

Antipneumococcus serum, Type I, was not used, as no Type I pneumococci were isolated.

Vaccines have not been used either prophylactically or in the treatment of the epidemic cases, as it seemed to us that there was no reasonable hope of benefit to be derived from their administration.

Coagulen Treatment.—In view of the frequent bleeding, it was thought that some coagulant might be effectual in combating the hemorrhagic diathesis. One of us (Casper) suggested a trial of coagulen-Ciba. As the first few intravenous injections seemed to check epistaxis and blood spitting within twelve hours, its use was continued and the results proved gratifying. At one time, we were unable to obtain coagulen, and thromboplastin-Squibb was substituted. This preparation did not prove as effectual as coagulen, and its use was abandoned. The apparent result of coagulen treatment on the mortality rate is shown in Table 10.

It is evident that coagulen is ineffectual when administered to seriously ill patients in the late stage of the disease. This result was anticipated. But the low mortality, 6.5 per cent., in the unselected early group against the 36 per cent. general mortality for pneumonia in the epidemic, seems very significant, especially when considered together with the clinical observation that visible hemorrhage (epistaxis, blood spitting and metrorrhagia) appeared to be checked by the administration of coagulen.

By "unselected" in the unselected group, it is meant that the patients were not selected with reference to the mildness of the symptoms. They were selected in the sense that they manifested some evidence of hemorrhage.

We feel that the beneficial result was due to the prevention of further hemorrhage into the alveoli of the lungs. The pathologic evidence favors the view that the initial pulmonary pathology of the lobar pneumonia type is a hemorrhagic edema. Several of the patients to whom coagulen was given had had a sharp rise of temperature during defervescence of the initial attack, they had begun to expectorate bloody sputum, and the characteristic explosive shower of fine râles could be heard over a large localized area about the angle of the scapula. After the coagulen injection, the blood spitting ceased, no physical signs of consolidation of the involved area developed, and the patients made a rapid recovery. However, roentgenographic examination made early in convalescence showed that there had been considerable central consolidation of the lung in the area where the râles were heard.

TABLE 10.—RESULTS OF COAGULEN TREATMENT

	Cases	Deaths	
		Number	Per Cent.
Total patients treated	70		
Unselected cases, early lobar pneumonia type	16	3	6.5
Selected cases, late, seriously ill, lobar pneumonia type	7	7	100.0
Total deaths from coagulen-treated pneumonia patients	..	10	18 9

Comment.—The modus operandi of coagulen action is not clear. Our laboratory tests, which are incomplete, do not show, with one exception, a delayed coagulation time, though postmortem findings indicate that such is the case. Further tests may correct those we have made. If the blood dyscrasia were due to platelet deficiency, the action would be more difficult to explain, for platelet deficiency can be effectually combated, so far as is known, only by the transfusion of fresh whole blood. Counts of the platelets were not made. However, the "bleeding time" was not prolonged in the tests made, and therefore platelet deficiency seems unlikely. Blood smears did not show any apparent decrease of platelets.

We are aware that Hanzlik,[3] in testing coagulen, administered intravenously to bleeding dogs, found its influence on the hemorrhage variable, and that the results ran parallel with the effect on the blood pressure. But his experiments were made with presumably healthy dogs in whose blood no element of coagulation was lacking. It is probable that these experimental data do not indicate what might happen in a blood dyscrasia due, for example, to prothrombin deficiency, which coagulen might remedy.

We wish to emphasize that we hold no brief for coagulen to the exclusion of other coagulants. It has been found to be a convenient and apparently efficient remedy. But it is quite possible, and indeed probable, that some other antihemorrhagic agent may be more efficient. We attribute the results obtained solely to its influence on the hemorrhagic diathesis, and we would suggest that other remedies that have given apparently good results (convalescent serum, horse serum and polyvalent antipneumococcus serum) act in the same manner.

---

[3] Hanzlik, P. J.: Journal Pharmacol. and Exper. Therap., 1918, 12, 119.

We have prepared coagulen for intravenous injection by dissolving 1.5 gm. in 30 c.c. of distilled water or salt solution, making a 5 per cent. solution. This is sterilized by boiling two minutes and the cloudy preparation is not filtered.

With the first lot used, no reactions were observed following the injections, but with the second lot a chill and increased fever frequently followed. On the following day the fever usually dropped to or nearly to normal. In other words, there seemed to be a reaction similar to the reactions following intravenous typhoid vaccination, proteose injections, etc. The result appeared to be beneficial, but we do not advocate using coagulen from this point of view, and we would prefer, at present, not to induce the "chill and fever shock," for the mechanism of its beneficial action and the conditions of safety are not understood. However, in our cases it has done no harm.

SUMMARY

1. The epidemic of acute respiratory infections numbered about 3,000 cases. A secondary pneumonia developed in 408 of the cases, an incidence of about 14 per cent. There were 147 deaths from pneumonia, a mortality of 36 per cent. for the pneumonia series, and of about 5 per cent. for the epidemic.

2. Hemorrhage was a prominent feature of the epidemic cases. Epistaxis was common, blood spitting and even hemoptysis occurred in the pneumonia cases, metrorrhagia was the rule in female patients, purpura of the skin occurred several times, and necropsies showed a fluid condition of the blood and hemorrhagic edema of the lungs. There was, therefore, clinical evidence of a hemorrhagic blood dyscrasia. Laboratory tests to determine the nature of the dyscrasia did not furnish conclusive evidence.

3. Leukopenia was constant during the initial infection and during the early stage of pneumonia. It persisted throughout the course of most of the fatal cases of pneumonia, but during the course of the nonfatal cases the leukocytes gradually rose to from 10,000 to 24,000. The conclusion was reached that the initial infection exerted a depressant influence on the bone marrow, while the secondary pneumonic infection tended as usual to stimulate the production of leukocytes, which increased in number as the primary influence waned.

4. The secondary pneumonias divided themselves into two types: (1) the lobar pneumonia type, and (2) the bronchopneumonia type.

5. Bacteriologic studies threw no light on the etiology of the initial infection. *B. influenzae*, pneumococci (nearly all of Type IV), and streptococci were the predominating organisms found. It is believed that the virus of the initial infection of the epidemic is still unknown; that the secondary lobar pneumonias were due to pneumococci and streptococci, pneumococci predominating, and that the bronchopneumonias were due to [illegible]

6. Treatment of the hemorrhagic diathesis by the intravenous injection of coagulen appeared to be effectual. This treatment was effectual only in the stage of the initial infection and in the early stage of the lobar pneumonia type of the secondary pneumonias. It is of no value in the late pneumonias.

ACUTE MENINGOCOCCIC ENDOCARDITIS AND SEPTICEMIA *

E. B. KRUMBHAAR, M.D. (Philadelphia)

FRANCE

Although the portal of entry of the meningococcus has never been demonstrated, the evidence in favor of the nasopharyngeal route to the cerebromeninges has been so strong that it has been more or less generally accepted. Whether, however, it reaches the meninges by way of the blood stream or more directly by the olfactory nerves or ethmoid sinuses is still a much discussed detail. A growing list of cases of meningococcic septicemia (Baeslack and collaborators,[1] Raffaelli[2] and others) and a few acute meningococcic endocarditis (Worster-Drought and Kennedy,[3] Cecil and Soper[4]) have now been reported.[5] Furthermore, the type of initial fever and the finding of meningococci in the petechiae and elsewhere indicate that in many cases at least the infection is temporarily generalized (Netter[6]) and the occasional isolation of meningococci from the blood prior to their detection in the spinal fluid is added proof that the route of entry from the nasopharynx is probably the blood stream. It would seem probable that, just as typhoid and pneumonia (which start as local diseases of the intestine and lung) are for a short period true septicemias with occasional lesions of distant parts, so also the meningococcus invades the whole system, but in the majority of cases eventually exerts a selective affinity for the meninges. In a few the septicemic features may persist and overshadow the meningitic element (Nankivell[7]) or even cause death without either clinical or postmortem signs of meningitis (Herrick,[8] Pybus,[9], Andrewes,[10] and Cecil and Soper[4]).

Such facts as the foregoing have led Herrick to believe that the disease is not primarily a meningitis, and that "meningococcic sepsis," or "spotted fever," are better terms than "epidemic cerebrospinal meningitis." Similarly he believes that intravenous serum treatment should precede and is more important than intraspinal injections. Whether or not further investigations will support this extreme view, the following three cases, occurring within a year among sixteen cases of cerebrospinal meningitis, may add weight to the already imposing list of this type of case:

REPORT OF CASES

Case 1.—*Clinical History.*—Private S. M., aged 28, had been in the service eleven months and in France four months. His past history was negative, except for occasional attacks of bilious vomiting and furunculosis. His present illness began suddenly with rigor followed by pyrexia and vomiting. The patient stated that he had very severe pains in the back of the head and neck and pain in the back. The pain in the neck was greatly aggravated by motion and radiated down the spine. Pain was also felt in the shins. The heart and lungs were normal. The vomiting continued for several days, jaundice appearing on the fifth day. Pyrexia continued between 101 and 102 F. and the pulse from 80 to 90 per minute. On the seventh day of the disease, a generalized purpuric eruption appeared all over the body, most marked on the limbs (that is, five days later than in Case 2). The leukocyte count at this time was 35,000, and a lumbar puncture gave a turbid fluid, under pressure, with numerous polymorphonuclear leukocytes but no organisms. The next day the patient complained of intense headache and pain in the back of the neck. There was distinct muscular rigidity. The abdominal reflexes were normal, and a slight Kernig's sign was obtained. The Babinski reflex was negative. The purpuric eruption remained unchanged. The eye grounds were normal and the patient was conscious. For the next few days the temperature remained about 103. The patient was drowsy and swallowed with difficulty. The petechial hemorrhages became larger and more extensive. A blood examination at this time (fourteenth day of the disease) showed 48,000 leukocytes (polymorphonuclears, 94 per cent.; small lymphocytes, 4 per cent.; large and transitional cells, 2 per cent). On the following day there was paralysis of the muscles of the left arm, and by the eighteenth day of the disease the patient was unable to swallow. With the exception of the paralyzed muscles, there was general spasticity of the body, the petechial eruption remained the same, and subconjunctival hemorrhages appeared in both eyes. Respiration became more labored; and though the meningeal symptoms seemed lessened during the week, fever continued and the patient gradually failed, till death occurred on the nineteenth day of the disease.

Nine lumbar punctures were made, and each withdrawal of spinal fluid was followed by intrathecal injection of 30 c.c. of curative serums (two of Pasteur's, four of Lister's polyvalent, and three of Gordon's Type II serum). Type II meningococcus had been isolated from the spinal fluid both at the casualty clearing station and the base hospital independently. In addition as the patient's condition at one time seemed more septicemic than meningitic, one intravenous injection of 30 c.c. of Gordon's Type II serum in 1½ pints in physiologic sodium chlorid solution was given.

Laboratory Examinations.—Daily lumbar punctures gave in the beginning an excess of pearly, turbid fluid, with 96 per cent. of polymorphonuclears, and on standing a heavy, yellowish, purulent sediment. Gram-negative, intracellular diplococci were found without difficulty in the first two smears. On trypsin agar plates there were a few viscid, white colonies, which grew on agar only at incubator temperature, gave acid on glucose and not on saccharose, and agglutinated up to 1 : 400 with Type II (Gordon) antiserums and slightly with Type IV antiserums. From the third puncture on, the spinal fluid was clear and colorless, and no organisms were obtained in either smear or culture. (On the last smear examined, from fluid taken shortly before death, two large clumps of apparent meningococci were observed.)

Necropsy.—There were numerous petechiae, not only of the skin, but also of the pleura-pericardium, and peritoneal covering of the stomach and liver, and of the mucosa of the stomach, intestine, the pelvis of kidney and the ureters. The heart was of normal size and color. On the posterior aortic valve was a rather soft, flat, grayish vegetation, 3 mm. in diameter, and on the anterior aortic and both mitral valves, several soft, glistening, yellowish, minute spots, that were easily wiped off. Smears from these valves showed numerous polymorphonuclears and many large, round, gram-negative cocci, mostly in pairs, both intracellularly and extracellularly. Smears from the heart's blood and pericardial fluid gave similar results. Examination of the brain and cord showed a slight excess of clear, serous fluid, but no gross microscopic signs of meningeal inflammation or exudate. A smear of subpial scrapings showed a few polymorphonuclear and intracellular meningococci. The other organs showed nothing noteworthy except areas of intense congestion of the kidney, liver and spleen, and localized infiltration of leukocytes and beginning hyaline change in these organs.

Case 2.—*Clinical History.*—Lance Corporal L. D. D., aged 23, three years in the service and two years in France, with negative history, was taken suddenly ill, on April 4, 1918, and soon developed a temperature of 104 F. with rapid pulse and muttering delirium, alternating with periods of irritability. He did not vomit, the pupils were equal, and there was no squint. The patient's condition was generally spastic, and he quickly sank into what was termed a "typhoid state." There was incontinence of urine. On admission two days later the temperature was 102, pulse 140. The patient was comatose, breathing heavily, the pupils were sluggish, slightly dilated and equal, and at no time could he be aroused. The tongue was coated and moist. There was no vomiting. There was general muscular spasticity. The head was retracted and the neck rigid, while in the muscles of the face were numerous fibrillary contractions, although there was no general convulsion of the body. Incontinence of the urine continued. The bowels were constipated. A petechial rash was profusely distributed over the chest and abdomen, but especially the limbs. The following day the temperature was 102, respiration 66 and pulse 140, death taking place on the afternoon of the 7th, after an illness of about seventy-two hours.

Laboratory Examinations.—The first lumbar puncture was made at No. 2 Stationary Hospital on the second day of illness. The spinal fluid was found to be under pressure, having a slight opalescence. The centrifuged deposit of pus contained a few gram-negative diplococci. During the evening of the same day 30 c.c. of Lister Institute polyvalent automeningococcic serum were given intravenously. The following morning 50 c.c. of clear spinal fluid were removed at this hospital and 30 c.c. of the same polyvalent serum injected intrathecally. The centrifuged specimen of the clear fluid showed a moderate number of gram-negative diplococci, chiefly intracellular, and gave a few characteristic colonies on trypsin agar. These fulfilled the various cultural requirements, but agglutinated with all four of Gordon's type antiserums up to 1 : 400.

Necropsy.—Twelve hours later, no gross evidence of a lesion of the brain or cord or meningeal exudate could be detected. Histologically, the only sign of meningitis present was an occasional leukocyte beneath the pia mater. Near the bases of the mitral leaflets there were numerous minute, glistening vegetations, which could easily be wiped off. Smears from these gave numerous polymorphonuclears and endothelial cells and many gram-negative diplococci. Smears from the heart's blood also showed gram-negative cocci, arranged in pairs and short chains of pairs, and gram-positive rods. Rather marked areas of round cell infiltration were present in the liver and kidney parenchyma, with bile staining of central cells of the liver lobules and fibrous obliteration of some of the kidney tubules and glomeruli.

Case 3.—*Clinical History.*—Private P. W. K., aged 23, was admitted to the hospital after an illness of twenty-four hours with a history of stupor and rigidity of the neck. The temperature was 102.2 F., pulse 78, respiration 38. The past history was negative. On admission the patient was semiconscious, with rigidity of the neck and back and pain in the head and back, and the temperature was 97. The patellar reflexes were normal. Babinski's and Kernig's signs were absent, although the latter had before been well marked. A pronounced petechial rash was present over the shoulders and chest. The lungs were clear and no cardiac murmurs were detected. The following day the temperature was normal, respirations were labored and cyanosis was present. The patient at times was delirious, but for the most part remained quiet in a state of semiconsciousness, responding to questions, when addressed. During the night the pulse became much more rapid and weaker. Tracheal râles were marked and the patient died next morning after an illness of four days. The petechial eruption remained the same throughout.

Laboratory Examinations.—Three lumbar punctures were performed. On the first two occasions more than 75 c.c. of turbid fluid were withdrawn, and from each sample a few intracellular diplococci were found by smear. On trypsin agar on the first occasion a rich growth of pale, viscid, characteristic colonies was obtained, but while these behaved normally on agar, they failed to produce acid on glucose as well as on saccharose. Agglutination tests were not tried. The third lumbar puncture gave 20 c.c. of clear, dark, brownish fluid. Like others it contained a few intracellular organisms, but failed to grow on trypsin agar cultures.

Necropsy.—The spinal pia mater was considerably thickened (2 mm.) and its inner surface bathed in pus. The cerebral and cerebellar pia was thin and transparent, but in the spaces over the large fissures there were distinct collections of pus. Smears from both brain and cord meninges gave numerous polymorphonuclears and numerous large gram-negative diplococci, chiefly intracellular. The cut surface of the cerebrum presented a typical "shaven beard" appearance of minute hemorrhages. The heart was pale and flabby, with some dilatation of the right chambers. A few pin point glistening spots on the mitral valve were shown by smear to contain leukocytes and a moderate number of gram-negative diplococci. There was also an acute staphylococcic pleurisy and confluent bronchopneumonia of the right side. There was a cloudy swelling and congestion of the viscera.

COMMENT

Besides the occurrence of acute vegetative endocarditis in all three cases, and the natural accompaniment of meningococci in the blood stream, there are a few details of the cases to be emphasized. The early appearance of the petechial rash in all, and the isolation of the gram-negative diplococci from the petechiae in the only instance tried, may be taken as evidence of the early generalization of the infection through the body. In such cases, therefore, the early appearance of the petechial rash should be taken as an indication for early intravenous injection of specific antiserum. The earlier form of macular rash that has occasionally been described was not mentioned in the case histories, and the opportunity for determining its presence had passed when the patients had reached this hospital. The lessening of meningeal symptoms in Case 1, and the absence of signs of meningitis at necropsy show the local success of the specific intrathecal treatment. The necessity for intravenous treatment in this case was also realized, but its futility in the presence of acute valvular vegetations needs no further comment.

The presence of intracellular meningococci in the spinal fluid in Case 3 after they failed to grow on trypsin agar is a not uncommon occurrence in this and other laboratories. Whether or not such organisms are to be considered dead or merely influenced in such a way that they will not grow under the artificial methods employed, is a point that cannot now be decided.

SUMMARY AND CONCLUSIONS

1. Three cases of fatal cerebrospinal meningitis, in which acute meningococcic vegetations on the aortic and mitral valves were found at necropsy, emphasize the importance of the possible septicemic factor in this infection.

2. The early occurrence of the petechiae in all three cases may be a useful indication that in similar cases a septicemia has been established, and intravenous as well as intrathecal medication thereby indicated.

3. In the ordinary nonfulminating, nonpetechial type of meningococcus infection (whether or not meningococci have temporarily entered the blood stream), the chief pathologic lesion being undoubtedly in the meninges, the chief route of specific treatment should be intrathecal.

4. The disappearance of meningitic symptoms, with persistence of signs of septicemia, should be an indication to substitute intravenous for intrathecal treatment, although if actual vegetations are present on the valves, it will rarely, if ever, be successful.

5. If, as in cases quoted in the literature, the presence of meningococci can be determined in the blood stream before the onset of meningitis, intravenous treatment may abort an otherwise fulminating case, and should certainly be used.

6. Meningococci may persist in smears from the spinal fluid after they have failed to grow on suitable mediums; but even if they are absent in both tests, specific therapy should be continued until meningitic symptoms have disappeared.

EFFECT OF TYPHOID LIPOVACCINE IN INCREASING SUSCEPTIBILITY TO OTHER DISEASES

ANIMAL EXPERIMENTAL EVIDENCE *

EDGAR M. MEDLAR, M.D., (Boston)
First Lieutenant, Medical Corps, U. S. Army
WASHINGTON, D. C.

From time to time since the use of typhoid vaccine as a prophylactic in the control of typhoid fever, there have been objections on the part of medical officers to its use, the main one being that it predisposes the individual to infection with other diseases. The practical importance of such objections can readily be understood now that our army has reached its present proportions. This series of animal experiments was undertaken in an attempt to increase our knowledge

from the experimental side of the effect of typhoid vaccine in lowering the resistance to infection.

Because of the importance that *Streptococcus hemolyticus* infection assumed in the cantonments in 1917-1918, it was thought advisable to take the hemolytic streptococcus as the infecting agent. The strain (No. 23) used was one obtained from a case of empyema at Camp Merritt, N. J.

The animal chosen as the test animal was the mouse, because of its susceptibility to the streptococcus, as well as its availability in the numbers needed.

The first problem to be solved was to get a constant dosage of streptococcus that would kill the minority of the control animals inoculated. It is well known that streptococci can be made highly virulent for mice, i. e., 0.000001 c.c. of an eighteen hour broth culture will kill constantly, and that on subcultures this virulence is rapidly lost. Because of this fact it seemed more practical to raise the virulence and then through subcultures over a considerable period of time establish a dosage of low virulence which would be fairly constant. This is what was done, and Table 1 gives the results obtained for a period of six daily inoculations.

The technic used in order to get a fairly constant growth was as follows: Plain bouillon, reaction + 0.3 to 0.5, was the medium used. A large number of tubes, each with 10 c.c. of bouillon, were prepared from a single lot of beef infusion, and this lot was used throughout the experiment. Subcultures were made daily by transferring one loopful of a twenty-four hour growth. Mice inoculations were made intraperitoneally with a bouillon dilution of a twenty-four hour bouillon growth.

From Table 1 it will be seen that the dosage which would show increased susceptibility best would be

0.01 c.c., and this was the dosage of low virulence adopted for the series of inoculations.

In order to get a broader view of the effect of typhoid vaccine on lowering the resistance, it was decided to have three series of mice, inoculated at intervals of several days, in each experiment.

Mice were inoculated subcutaneously with the standard triple typhoid lipovaccine used in all the camps. The dosage was sufficiently large to cause all the animals to be sick and quite a high proportion of them to die, the idea being to lower their resistance as much as possible. If proportionate dosage were given man it would amount to several hundred c.c., while the dosage actually given is only 1 c.c. Tables 2, 3 and 4 give the data and results of the experiments.

It is probable that under ordinary conditions it is the hemolytic streptococcus of relatively low virulence that is encountered in the camps. In those camps, however, in which more or less of an epidemic of streptococcus infection prevailed, the virulence of the streptococci probably was much increased.

With this in view, a part of the series of mice shown inoculated with typhoid vaccine in Tables 3 and 4 were inoculated with the same strain of streptococcus used for low virulence, which had been raised in virulence through mouse inoculation. Tables 5 and 6 give the data and results of these experiments.

COMMENT

In animal experiments, in which there are always uncontrollable factors to deal with, the only way any reliable results can be obtained is to repeat the experiment. If the same results are obtained consecutively, conclusions may then be fairly drawn. Results of the experiments as a whole should be considered rather than any individual portion, as there would be less chance of wrong deductions when the mass is considered. For example, in Table 3, comparing Series 1 with the controls, one could argue that there is increased susceptibility; comparing Series 2 and the controls, arguments for increased resistance could be brought forth; but taking the experiment as a whole, it will be found that there is practically no difference when Series 1, 2 and 3 are averaged against the controls; and this is without doubt more nearly the truth.

The number of typhoid vaccinated mice inoculated with low virulent streptococci were 111, of which twenty, or 18 per cent., died. Thirty-six control mice were inoculated with low virulent streptococci, of which ten, or 27.8 per cent, died. There is a difference here of 9.8 per cent. in favor of increased resistance to the streptococcus in the mice inoculated with typhoid vaccine. It may be possible, however, that the typhoid vaccine killed some of the mice most susceptible to the streptococcus and that this difference is more apparent than real.

Thirty-three typhoid vaccinated mice received inoculation of highly virulent streptococci, and of these twenty-two, or 66⅔ per cent., died. Thirteen control mice were inoculated, and nine, or 72 per cent., died. Here again there is a percentage in favor of increased resistance to the streptococcus, but it is possible that this difference may be more apparent than real.

There is one point, however, that may account for this apparent slight increase in resistance to the streptococcus. Following typhoid lipovaccination in man there is a moderate mobilization of leukocytes lasting for a few days. This undoubtedly occurs in animals, and it is generally thought that the leukocyte is the chief factor of defense against the streptococcus. *Another point that would favor the view that an increased resistance to the streptococcus follows inoculation with typhoid vaccine (one form of foreign protein) is Jobling's contention that there is a general immune reaction following the introduction of foreign protein.*

CONCLUSIONS

There is no evidence that there is increased susceptibility to streptococcus inoculation in mice following typhoid vaccination. There is a slight amount of evidence in favor of increased resistance to the streptococcus possibly due to the mobilization of the leukocytes. It is probable that these facts will be applicable to other vaccines and other diseases, for in a series of thirty-two mice vaccinated against pneumococcus, similar results have been obtained.

WAR NEUROSES, SHELL SHOCK AND NERVOUSNESS IN SOLDIERS *

PEARCE BAILEY, M.D. (New York)
Colonel, M. C., U. S. Army; Chief, Division of Neurology and Psychiatry, Surgeon-General's Office.
WASHINGTON, D. C.

A recent visit to France and England furnished me with opportunities for observing the various phases of war neuroses, shell shock and nervousness in soldiers. In France the patients were seen at *triages*, or sorting stations, field and army, and base hospitals. Those seen in England gave as a rule longer histories and were satisfactorily separated from the front by a stretch of salt water. In both countries, facilities for studying the different methods of treatment and management were made freely available to me, and I also was able to profit by the views of medical officers of long experience in these matters. The present article is a summary of the impressions gained from this visit

IMPORTANCE OF NEUROLOGIC SUPERVISION

The neurologic problems of war have assumed an importance quite undreamed of, and the necessity of neurologists for a modern army is receiving general recognition. In battle areas the need of neuropsychiatry exceeds that of general medicine, as the nervous and mental casualties may exceed 10 per cent. of the total casualties. France maintains 20,000 neurologic beds in the rear, most of which are occupied by functional cases, and at the front tries to maintain one and one-half neurologic beds for each thousand troops. Major Arthur Hurst, R. A. M. C., estimates that 26,000 beds are occupied each year in Great Britain by purely hysterical patients. The previously held neurologic conception that hysterical paralysis and contractures did not occur in conjunction with physical wounds has been completely overthrown, as the war has demonstrated that functional disturbances of this character complicate surgical injuries with frequency. The longer the war goes on, the more it becomes evident how widespread are the effects of functional nervous disease both in combatant troops and in patients hospitalized for any cause.

---

* The cessation of hostilities and the proposed rapid demobilization of the Army have rendered many of the war time methods of the treatment of "shell shock" impracticable. This article should be read as of the time when it was written, that is, as of a time when no end of the war was in sight.

The web of mystery and vagueness that enveloped the entire shell shock group in the initial phases of the war has been swept away, and now there is an essential agreement of opinion that the great bulk of the cases are functional, that it is possible to prevent the occurrence of many of them, and that, even when of long standing and fully developed, they are curable. Actual experience has now shown that a substantial proportion of the nervous cases which appear at the front can be so managed that they do not run on into neurosis. The preventive measures are most sure of success in the battle areas, where they can be instituted almost immediately after the occurrence of the casualty. It is believed that from 80 to 90 per cent. of the patients of this class can be returned to the lines if they are promptly cared for in small neurologic units directly connected with the armies. The prevention of the cases that originate in the base hospitals is more difficult, but can be greatly furthered by a diagnostic alertness of medical officers on the lookout for the first manifestations of hysterical symptoms. It has also been proved that chronic, long standing cases, whether developed at the front or in base hospitals, can also be effectively cured, although the therapeutic arrangements for cases of this character are more elaborate.

It is thus seen that the outlook for the war neuroses is much brighter than it was. At one time it seemed impossible to stem the flood of these cases or to devise means of rehabilitating the patients. But in spite of this favorable change in the situation, shell shock still remains an actual as well as a potential problem for the medical department. Its potentiality can be held in check by efficient medical officers acting at the right time and place; but it will always be actual. There will always be many soldiers whose nervousness cannot be controlled at advanced points, either on account of the essential character of the nervousness itself or because, in the rush of warfare, it is impossible to carry out medical policies, desirable in themselves, but incompatible with the main object in hand.

In our army the task of the cure of the patients is difficult by reason of the sweeping application of the principle of compensation for disability. Article III, Section 300, W. R. I., Act of Oct. 6, 1917, as amended June 25, 1918, provides that officers and enlisted men or other members shall be taken to have been in sound condition when examined, accepted and enrolled for service, and thereafter entitled to compensation under the act for disability. Thus, as far as compensation is concerned, line of duty may be held to include all insanities, feeblemindedness, epilepsy, etc., irrespective of their having preexisted or not. Legally, no disorder can have preexisted in a person accepted for military service. As far as the neuroses are concerned, this law puts it beyond the power of medical officers to throw any doubts into the mind of the patient that he will surely be compensated if he persists in his neurosis long enough.

It is believed that the great success of the French with their neuroses is due to the fact that the neuroses are not pensionable and that no soldiers are discharged for such cause. The first factor is not available to us, but the second is; and for economic reasons alone every effort should be made to effect cures in neurotics, so that, even if they discontinue the service, they cannot claim disability on their return to civil life.

It was at one time thought that the doing away with the term "shell shock," with its implication of organic injury, which impresses the mind of the patient and the public alike, would help in the treatment. But it seems now as though the term had entered too deep into the language to be done away with. Efforts to offset the bad effects which the introduction of the expression brought with it will probably have to be expended in making it generally known that shell shock is an essentially curable condition.

CAUSATION

No entirely satisfactory explanation has been offered for the unprecedented frequency of these neuroses in this war. The great increase in the number and intensity of explosives does not altogether explain it, as they develop after gassing, after machine gun firing, and perhaps oftenest when there has been no direct exposure to firing at all. They develop in the base hospitals in France, and practically all of the symptoms quoted as war symptoms have been observed in the home cantonments during the training period. Neither does it seem probable that it is an entirely new development of this war, but rather that it existed in earlier wars in smaller numbers surely, and probably under a variety of names—in our Army, nostalgia, perhaps. Also in view of the fact that absenteeism as an idea has a foreplace in the minds of both officers and men whose sole reason for discharge is a war neurosis, it seems probable that among the 600,000 cases of absenteeism reported from the Union Army during the Civil War, an absenteeism which took the form of desertion or removal of patients from the medical services by friends or committees, there might have been found a numerous representation of modern shell shock.

The factor of predisposition is not to be denied in considering the causation of these conditions, but it is generally believed that it is sufficiently marked in most cases to have justified the rejection of the recruit.

With the exception of epilepsy, no single disease has been demonstrated as being an essential factor in causation. However, a diminished resistance may be inferred from the fact that the larger number of cases are observed during the first few months of service, although it must not be forgotten that there are a great many cases in which the soldier has not only given long service, but has also been distinguished for his morale and his bravery. It is not uncommon in French hospitals to see hysterical patients personally decorated and also wearing the *fourragère*.

Neuroses are credited with being more frequent in the infantry in common with other casualties, and also more common in trench warfare, although the latter has not been the case with our troops. The early impression that they were more common among officers has not been borne out by later experience. In a small proportion of the total number of cases the individual has been exposed to a traumatism severe enough to have caused lesions of the central nervous system without external wound. It is needless to state the uncertainty often surrounding the actual occurrence of injuries; but the injuries of the nervous system may be verified by definite signs. It is unfortunate that these relatively infrequent organic cases came to notice so early, as largely in consequence of them the idea became fixed that shell shock was an organic condition and so to be regarded quite differently from those functional conditions that are the result of suggestion and are curable by psychotherapy. There has been reproduced what happened when the nervous effects of railway accidents first came into prominence. The new name, the new circumstances, the malassortment of diverse clinical conditions into one group, and the permitting of the group to carry the stigma of the most serious cases, which were the least frequent, the failure to recognize the material motive as a powerful provoking and sustaining motive—all these circumstances combine to make the history of shell shock a repetition of the history of railway spine.

On the factor of exhaustion too much emphasis can hardly be laid. The break is often preceded by weeks of disturbed sleep, due to bombing and artillery fire, and during an advance the story is common of several days of excessive exertion, nervous strain, no sleep at all, exposure to cold, only cold food and but little of that. The wish to be out of the war, which all along may have been latent, comes more to the surface when the shaken soldier staggers to or is brought to the first aid station or when he emerges from a period of unconsciousness. Under the influence of food, rest and encouragement, this imperfectly formulated wish may sink back of itself or may require additional efforts on the part of the medical officer to make it recede. This period, this interval, is one of greatly exaggerated susceptibility, and during it the most trivial circumstance may petrify the idea of illness, and a way out by means of it. But it is also a period when the kind, firm and confident attitude of the medical officer may completely reassure the shocked man as to his ability to carry on again and inspire in him the firm intention to do so.

CLINICAL VARIETIES

After the elimination of all totally foreign conditions, such as mental disease, organic nervous disease, and endocrinopathies, the war neuroses may be roughly divided into three general classes, between which occurs the same overlapping as is seen in the neuroses in civil life. These classes are: A, concussions; B, neuroses of neurasthenic or psychasthenic type, and C, hysteria.

A. *Concussions.*—These justify the assumption of the existence of minute and more or less disseminated lesions of the central nervous system, and may be accompanied by such symptoms as unconsciousness lasting for several days, retention of urine, loss of knee jerk, blood in spinal fluid, paraplegia, etc. Some patients of this class recover perfectly within a few weeks; others do not recover satisfactorily, and still others develop the symptoms of neurosis, illustrating the relationship between organic and functional disease.

B. *Neuroses of Neurasthenic or Psychasthenic Type.*—These may develop as a result of concussions, but as a rule their origin cannot be connected directly with any physical injury. They differ in no essential particulars from the neuroses of civil life except that they carry a strong coloring of the war situation. Many of them are associated with symptoms suggestive of endocrine disturbance, and the thyroid picture, especially in gas cases, is much in evidence. Thus, in addition to the symptoms of fatigue, lack of confidence, phobias, compulsions and general hyperesthesia are observed rapid pulse, cardiac irritability, pain over the heart, vomiting, and terrifying dreams with war content.

C. *Hysteria.*—Babinski's conception of hysteria as a condition produced by suggestion and curable by psychotherapy has been of inestimable practical value at this time, not only in showing the correct management of hysteria *en masse,* but also in bringing to the light the frequency with which hysteria lays its crippling hand on conditions not primarily neurologic. A brief historical retrospect may help to an understanding of this subject, which has gained so much in importance during this war.

The creation of hysteria as a clinical entity must be credited to Charcot. He assembled old observations and made new ones, and left the picture of a characteristic disease with a definite symptomatology. He recognized the essentially suggestible nature of hysterics, but he did not define the origin of the suggestions, nor did he indicate the means by which they might be avoided. His influence was enormous, extending to teachers and authors of all nationalities, so that at his death hysteria was accepted, practically all over the world, as he had fashioned it. But he showed no practical way out.

For the past twenty years Babinski has been destroying the disease which Charcot created, leaving more or less to one side the personality of hysterics. He has shown that the classic symptoms of hysteria are the results of suggestion originating in medical examinations, or from misapplied medical or surgical treatment. As a proof of the correctness of his view, it is stated that the "grande hystérie" of the Salpêrière has now practically disappeared from the French clinics.

Babinski, like his illustrious predecessor, has exercised a great influence on the medical profession of France, and at the outbreak of the war it had practically adopted his view on hysteria. The advantage to France from this was that its medical officers were from the first in a position to realize how hysterical symptoms arise and how they can be cured.

Among the symptoms that may be mentioned as being produced by suggestion are deafness, blindness, mutism and deaf-mutism, tremors, contractures and paralyses. Some few of these, such as deafness and mutism, which are so closely connected in consciousness with states of terror and in which the original insult is in itself a powerful suggesting factor, come on immediately; but the development of the larger number is delayed for days or weeks during the period when the patients are particularly suggestible and are exposed to the suggestions of medical men who examine them, and to the suggesting example of other sick and wounded. It is at this period particularly that the wisdom and discretion of medical officers can accomplish so much in suppressing the tendencies to the development of disabling symptoms.

A particularly interesting condition, which has first received detailed attention during this war, is a peculiar form of contracture affecting arms and legs, especially the feet and hands, which develops in sequence to some minor surgical injury. In these cases, various trophic disturbances are added to the functional incapacity. The exact pathologic condition in these cases is still not clear, but most of the patients are curable under carefully prepared psychotherapy.

TREATMENT AND MANAGEMENT

General Considerations.—The importance of a definite understanding as to discharge and compensation has already been emphasized. If the contrary to what is known to be wise maintains, if it is accepted throughout the Army that functional nervous disease is a grave disability which, if persisted in long enough, will insure a separation from the service under favorable pension conditions, the task of medical officers will become exceedingly difficult; not only will they miss an effective argument in influencing the minds of their patients, but they themselves will be affected by the atmosphere which tends to foster invalidism and make it comfortable. Except at the very beginning, except during the period of suggestibility before symptoms of neurosis have shown themselves, the hospital atmosphere should not be made too attractive for these patients. The attitude of medical officers should be that they are there for the express purpose of ridding the patient of his neurosis and firmly intend to do it, and the hospital itself should be organized along lines of strict war discipline. A war neurosis is a personal reaction to a military situation, and it must be cured in terms of the situation. It is an infantile reaction, and the medical officer must call to his aid some of the resources of the schoolmaster. A hope of reward should spur on the patient who lends himself readily to treatment and does well, and there should be some suggestion of punishment for those who are refractory and who tend to relapse.

In the advanced French centers the patients, even those who have been subjected to violent concussions, are told that they will soon be well again, and that the furlough, to which every French patient discharged from hospital is entitled, will make their cure perfect. If, however, the patient does not respond to encouragement of this kind, a different tone is adopted, and he is told that patients who develop nervous symptoms get no furlough. It is difficult to be specific in these matters or to lay down general rules, but the general rule is that the longer the patient persists in keeping on the road that leads to neurosis the more uncomfortable he will find it. It would be well if every one could grasp this view of the matter and could realize that the more discipline is relaxed, the more the patients are permitted to believe that they are suffering from serious disorders, the more of them will be found in soldiers' homes after the war. Such public utterances as that of a member of parliament to the effect that no soldier who had suffered from this terrible affliction should ever be asked to bear arms in France again injures the morale of troops and tends to postpone recovery in patients who under proper conditions might soon be well.

The whole difficult subject of discipline receives a certain illumination from a consideration of a system of management employed at certain French centers and known under the name of *torpillage.* Torpillage consists in the brusque application of galvanic currents, strong enough to be extremely painful, in hysterical conditions, and the continuance of the procedure to the point at which the deaf hear, the dumb speak, or those who believe themselves incapable of moving certain groups of muscles are moving them freely. The method has proved highly effective, and requires but little time and practically no personnel except the medical officer who applies the treatment and the noncommissioned officer who takes the patient at the end of the treatment and continues the exercise of the affected parts. One treatment suffices. The apparatus is of the simplest, the only accessory to the electric supply and the electrodes consisting of an overhead trolley which carries the long connecting wires the whole length of the room, thus making the patient unable to run away from the current which is destined to cure him.

This method is more cruel in appearance than in fact, as the contacts are brief and only a few are necessary. What it really consists in is giving authority to a medical officer to inflict pain on a patient up to the point at which the patient yields up his neurosis. Its unquestioned effectiveness carries a lesson which makes plain that under circumstances a military neurosis disappears under punishment. It substantiates what was previously said in reference to rewards and punishment. As far as punishment is concerned, it should never be presented to the patient as such. It should rather be explained to him as a certain form of treatment which is of necessity not agreeable. The most feasible means for the carrying out of this idea is isolation. All of the French centers have isolating rooms, locked on the outside, into which refractory patients are placed and shut off from companionship, reading and writing materials and tobacco, until such time as they show themselves amenable to treatment. Rooms of this kind are especially necessary and effective in the management of relapses. As a matter of practical fact, the knowledge that isolating rooms are on hand and available is usually all that is necessary. They are not often used, and in one center they were found given over to the lodgment of attendants. But the underlying idea should make plain that a stubborn war neurosis is cured by the physician's mastering the patient. In many, but not in all, patients, persuasive measures are sufficient; but when they fail, disciplinary measures should be made available; and the very knowledge that they are available will render it rarely necessary to make use of them. It seems probable that the reason so little of this variety of persuasion can be made use of with officers is that the treatment of neuroses in officers is generally difficult.

At the Front.—The general plan of the treatment of these cases at the front has already been given. Nothing further need be added here except to report that Lieut.-Col. T. W. Salmon, senior consultant in neuropsychiatry, American Expeditionary Forces, has perfected and made operative comprehensive plans for the early treatment, in direct connection with the armies, which have worked great good to our troops.

In Base Sections.—If rehabilitation of the nervous soldier fails at the front, cure is inevitably delayed. During the days or weeks of his being transferred from one hospital to another, he not only fails to receive appropriate treatment, but is exposed to the suggestions of illness which deepen the roots of a beginning neurosis. In all bases treatment is slower and less certain of effecting a return to the fighting line. It has been shown to be necessary to have hospitals specially organized as to personnel, general equipment and surroundings. If such hospitals are located in France, it is still possible in fairly recent cases to return patients to their original duty after a few weeks of treatment.

If, however, the patients are returned overseas, the chances of returning them to foreign service again are not good. With soldiers of this class returned home, England enters into a kind of agreement or understanding that they shall not be ordered to France again for a period of six months. Practically it amounts to an understanding that they shall not go to France again for the period of the war. But even if soldiers suffering from the neuroses are not expected to rejoin their expeditionary comrades, once they have reached home there nevertheless should be no relaxation of the principles of management in the home hospitals. The same principles hold good that the most humane thing for nervous soldiers is to hold them in the military service until they are cured. At home it may be expected at least to reestablish them sufficiently to enable them to do some work useful to the army during the war, so that the end of the war will find them able to resume their civil occupations.

It is to be the policy of the medical department of the American Expeditionary Forces to retain all the patients of this class in France as far as possible. But it cannot retain all of them in France, and sufficient numbers of them will be returned to necessitate the establishment of one or more special hospitals in this country, which should be organized with great care. They should be remote from large cities and situated in a locality of which the climate will permit outdoor occupation for the greater part of the year. One thousand beds is the limit of size, as the atmosphere of cure, which they must have, is difficult to maintain in larger units.

Whenever it is possible, the commissioned personnel should have had expeditionary experience, as an actual knowledge of conditions in France will strengthen the influence of medical officers over their patients. Men or women nurses may be employed, but should be selected with special reference to their attitude toward the patients which facilitates cure. The patients should be kept as constantly occupied as possible, and the occupations (indoors) should be of useful character, such as basket making, tailoring, shoemaking, typewriting and carpentry. Agriculture is the best outdoor occupation. Occupations are to be considered as an essential part of the treatment; in addition to their moral benefit, they aid in restoring facility to parts that have been paralyzed or the seat of contractures. Physiotherapy should be instituted with the same end in view. Setting up exercises are to be carried out by an experienced noncommissioned officer, and ladders, steps, bars, walking floors, etc., are to be arranged to overcome the effects of any local disabilities.

The principle behind all the procedures of physiotherapy should be that the patient is made to do them for himself as quickly as possible. He should be put on his own initiative, and overseen rather than watched. Massage, electricity and hydrotherapy have little part in the treatment. Massage has a place in case of atrophy, but as a general practice it is opposed to the main principle, which is that the patient is to prove to himself that he can do the things which he thought he could not do. Massage is opposed to that principle.

The classification of cases, to be made in the receiving ward, is extremely important. Neurasthenics and psychasthenics should be separated from the patients with local hysterical symptoms, as the methods for these two classes is different. Also, at the time of reception, an effort should be made to ascertain the general morale of the patient. Many show evidences of ill nature and resentment and come to the hospital with their minds made up that they will not be cured. Such are usually easy of identification, most betraying their intentions by malicious glances of the eye. If allowed to associate freely with well intentioned patients they are apt to corrupt the general morale of the ward.

As far as the treatment of the cases of actual concussion which have developed into neurosis, and the neurasthenic and psychasthenic cases are concerned, there is little new to be said. The treatment is that of the psychoneuroses in general with special reference to the military situation. Among the symptoms common to this class are insomnia, war dreams, vomiting, pains in the head and precordial pains. Stammering is often found in this class, and is reported as difficult to deal with. Cases with hysterical manifestations, such as aphonia, coarse tremors, paralysis and contractures require quite a different management. Such patients are to be given to understand, on reaching the hospital, if possible before reaching the hospital, that they have come there to be *cured,* and that they certainly will be cured at one sitting. This is the great practical demonstration of the war in psychotherapy, that hysterical conditions can be cured almost instantaneously, when proper arrangements have been made, even if the condition has lasted for years. The idea of a cure, of a crisis, seems to be the crux of the matter. It does away with the hospital idea of "care and treatment," and fixes a definite moment when the crippling effects of illness will disappear as quickly as though they had been cut away with a knife. The more completely the preparations are carried out to make the idea forceful, the more certain will the effects be.

There must be some air of magic about the performance. Examinations at this point are better brief, and if the diagnosis has already been established, would better be omitted altogether. Often the patients have already been examined too much. Elaborate history taking is also superfluous, as an intimate knowledge of the patient's case is not necessary before the cure, and is better obtained during conversations while the cure is being effected. The cure itself is effected by means of suggestion and persuasion, various methods being employed with equal success by different operators.

In all, with the exception of *torpillage,* the patient is put at his ease, assured that he will suffer no pain, made to relax, and in some way or other made to move the part that is paralyzed or contracted, made to speak, to hear, to cease tremors. Most operators avail themselves of a mild faradic battery to emphasize their suggestions; others use no artificial means at all. The time required for the cure varies from a few minutes to a few hours to all day and night. The principle is that once the physician has shut himself up with the patient he shall not leave him until the object is achieved.

PREPARATORY SUPERVISION AND AFTER-TREATMENT

Quite as essential as the cure itself is the period that precedes it and the period that follows it.

The first, the period of preparation, should be utilized to prepare the patient's mind for a favorable reception of the suggestions that are to cure him. With this end in view he is not treated immediately on arrival at the hospital, but is made to wait several days during which nurses, attendants and patients who have been cured tell him of the certainty of cure and its painlessness. In the treatment room of the Salins hospital there is a large pile of canes, crutches and orthopedic apparatus that have been discarded by cured patients, a pile well calculated to strengthen the faith of the doubting.

The period after the cure is devoted to careful supervision of the patient to the end that he keeps doing the things which a short time before he thought himself unable to do. A sharp lookout should be kept for relapses, and relapses should be dealt with with promptness and firmness. Military drills should be begun as quickly as possible, but the most satisfactory arrangement for a postgraduate course is a special training camp under the command of a line officer. Under present regulations a patient discharged from a hospital goes to a replacement depot without having been tried out under service conditions. But neurotics are too uncertain equations to be passed on without having first proved themselves. Unless fortified by an actual trial of the capacities of the patient, the decisions of classifying boards are apt to be erroneous.

Some explanation must be given as to the significance of cures and relapses. Cure means the disappearance of the symptoms that were created by suggestion and made to disappear by psychotherapy. Cure removes what was produced by a situation without any particular attempt to determine the mechanism of the production. It is quick and pragmatic and adapted to be applied to large numbers, as opposed to being time-consuming and analytic and individualistic. Those who favor the analytic school of mental medicine will doubtless deny, and with some reason, that the disappearance of one or more hysterical symptoms is proof of the cure of the patient. But to this may be answered that the cure of the patient begins with the removal of the obstacle that immediately prevented him from performing his duties. If, on such a removal, he is able to resume duties that tend to build up character quite as much as the explanations furnished by psychanalysis, he may be said to be practically cured.

The fact is that many patients treated in this way are able to carry on again. Roussy of Salins sends a goodly proportion of his patients back to the line in spite of the fact that most of them have been crippled for months or years. He is aided greatly by the training camp and also by the authority given him of recommending a change of service when he considers such a change necessary. For example, he often returns infantrymen to the artillery.

Relapses consist in a return of the symptoms in a patient once cured. The tendency to them is common, especially when the patient is removed from the care of the medical officer who effected the cure. Patients relapsing should be returned as soon as possible to the place of the original treatment, to the same medical officer, and as relapses are indicative of a bad morale on the part of the patient, of an unwillingness to profit by what he has learned, strict and if necessary disciplinary measures should be used.

New and Nonofficial Remedies

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application. W. A. Puckner, Secretary.

BENZYL BENZOATE.—Benzylis Benzoas.—$C_6H_5COO.C_6H_5CH_2$.—The benzyl alcohol ester of benzoic acid. It contains not less than 95 per cent. benzyl benzoate.

Actions and Uses.—Benzyl benzoate lowers the tone of unstriped muscle, and has been suggested as a remedy against renal, biliary, uterine, and intestinal colic and other spasms of smooth muscle, including angiospasm. Its clinical use is still in the experimental stage.

Dosage.—0.3 to 0.5 Cc. (5 to 7 minims).

Benzyl benzoate is a colorless oily liquid above about 20 C. It is odorless, or has a faint aromatic odor, and a sharp burning taste. It is insoluble in water or glycerin but miscible in all proportions with alcohol, chloroform and ether.

Benzyl benzoate boils at 340 to 350 C. with partial decomposition. When ignited it burns with a very smoky flame.

Specific gravity 1.09 to 1.13 at 15 C., 1.083 to 1.122 at 25 C.

Benzyl benzoate is neutral to litmus. It is readily saponified by alcoholic solution of potassium hydroxide. The solution obtained when neutralized yields a flesh-colored precipitate with ferric chloride solution, and upon acidulation a white crystalline precipitate of benzoic acid separates. This precipitate may be identified by extracting with ether and applying the usual tests for benzoic acid.

Ten Cc. benzyl benzoate should leave no weighable residue upon evaporation and heating until all carbon is burned away. To about 2 Gm. benzyl benzoate, accurately weighed, add 25 Cc. half-normal alcoholic potassium hydroxide solution and heat the mixture to incipient boiling under a reflux condenser for one hour. To the cooled solution add phenolphthalein and titrate the excess potassium hydroxide with half-normal hydrochloric acid. The volume of half-normal potassium hydroxide used should indicate not less than 95 per cent. benzyl benzoate (each Gm. benzyl benzoate requires for saponification not less than 8.9 Cc. or more than 9.4 Cc. half-normal alcoholic potassium hydroxide solution).

Benzyl Benzoate-H. W. and D.—A non-proprietary brand of benzyl benzoate complying with the tests and standards for benzyl benzoate.

Manufactured by Hynson, Westcott and Dunning, Baltimore, Md.

Solution of Benzyl Benzoate, Miscible-H. W. and D.—A solution of 20 Gm. benzyl benzoate in 78 Gm. ethyl alcohol to which is added 2 Gm. of powdered castile soap as an emulsifying agent.

Actions and Uses.—Same as benzyl benzoate.

Dosage.—1.5 to 2 Cc. (20 to 30 minims).

BARBITAL.—Diethyl-barbituric Acid.—Acidum Diaethyl-Barbituricum.—Diethyl Malonyl Urea.—Malo-Urea.—2,4,6,-trioxy-5-diethyl pyrimidin, $CO(NH-CO)_2C(C_2H_5)_2$. First introduced as veronal.

Actions, Uses, Dosage, Physical and Chemical Properties.—See New and Nonofficial Remedies, 1918, p. 95.

Diethylbarbituric Acid-Merck.—A brand of barbital complying with the N. N. R. standards.

Merck & Co., New York, distributors.

Diethylbarbituric Acid-Merck Tablets, 5 grains.—Each tablet contains diethylbarbituric acid-Merck, 5 grains.

BARBITAL SODIUM.—Sodium Diethyl-Barbiturate.—Sodii Diaethylbarbituras.—$Na(C_8H_{11}O_3N_2)$.—The monosodium salt of barbital (diethyl-barbituric acid).

Actions, Uses, Dosage, Physical and Chemical Properties.—See New and Nonofficial Remedies, 1918, p. 96.

Sodium Diethylbarbituric Acid-Merck.—A brand of barbital sodium complying with the N. N. R. standards.

Merck & Co., New York, distributors.

Sodium Diethylbarbituric Acid-Merck Tablets, 5 grains.—Each tablet contains sodium diethylbarbituric acid-Merck, 5 grains.

Fat Embolism as Factor in Traumatic Shock.—According to an abstract in the *Nederlandsch Tijdschrift*, H. Siegmund has reported that he found evidences of fat embolism in the lungs at necropsy after wounds with much shattering of bone or injury to soft parts. When there had been phenomena of shock, the fat embolism was the most pronounced and extensive, amply sufficient to explain the fatal outcome. In the prolonged cases the fat embolism involved the brain or was general.

SATURDAY, DECEMBER 28, 1918

The year 1918 has gone: a year momentous as the termination of the most cruel war in the annals of the human race; a year which marked the end, at least for a time, of man's destruction of man; unfortunately a year in which developed a most fatal infectious disease causing the death of hundreds of thousands of human beings. Medical science for four and one-half years devoted itself to putting men on the firing line and keeping them there. Now it must turn with its whole might to combating the greatest enemy of all—infectious diseases. In this battle there must be no armistice; no peace without victory. Here's wishing every member of The Journal family continuous courage in the glorious struggle, with victory succeeding victory, and to all a Happy and Prosperous New Year.

IS INFLUENZA DUE TO A FILTRABLE VIRUS?

The primary cause of influenza, in accordance with the facts as we now have them, is an unknown agent that prepares the way for secondary infections of the respiratory tract. Is this unknown agent a filtrable virus? The results of experiments just reported to the Academy of Sciences at Paris appear to indicate that it is. Nicolle and Le Bailly[1] inoculated monkeys (*M. cynomolgus*) with the bronchial secretions of patients in the early stages of typical influenza. One monkey, which received the unfiltered secretions under the conjunctiva near the papilla and into the nose, came down on the sixth day with a fever that lasted three days. The same secretion, diluted ten times with salt solution and filtered through a Chamberland candle (L 2) under a pressure of from 30 to 40 cm. of mercury, was injected subcutaneously into a healthy man, who fell sick on the sixth day with headache and general malaise, conjunctival injection and moderate fever, recovering after five or six days. The filtered material was also injected intravenously into a second person, but he remained well. Cultures of the filtrate remained sterile, showing that it was free from ordinary bacteria. A healthy man was injected subcutaneously with 3 c.c. of the blood of the monkey taken on the first day of the fever, but without any results. In another experiment, 3 c.c. of blood drawn on the second day of the characteristic attack of influenza were injected into a vein of a healthy person without any apparent result. Again, bronchial secretion obtained on the third day of the attack from a man suffering with influenza was injected under the conjunctiva and placed on the nasal mucous membrane of a monkey, and on the fifth day the animal developed a fever that lasted three days; after filtration the material was injected under the skin of a healthy person, who became ill on the sixth day with the symptoms of a mild attack of influenza. Intravenous injection of the filtrate into a healthy man produced no result. That the persons who came down with symptoms of influenza after having been inoculated subcutaneously with these filtrates did not suffer from the natural disease is indicated by the fact that they occupied particular quarters with other persons, none of whom became sick, and also because none of these inoculated became sick subsequently. From their results, Nicolle and Le Bailly conclude that the bronchial secretion in the acute period of influenza is virulent; that the monkey is susceptible to the virus by way of the subconjunctival tissues and the nasal mucosa, and that the virus is filtrable because sterile filtrate injected subcutaneously seemed to produce the disease in two persons. They failed to produce the disease by intravenous inoculations, which might be interpreted to mean that the virus does not survive in the blood.

However, an experiment reported by Dugarric de la Rivière[2] seems to show that the virus may be present in the blood. He mixed the blood from four persons who were severely ill with influenza, passed it through a Chamberland candle (L 3), and besides injecting rabbits, injected himself under the skin with 4 c.c. of the filtered blood. Nothing further is said at this time concerning the injections of the rabbits. Concerning the experiment on himself, however, he reports that there was no local reaction, but that on the third and fourth days after the injection he had marked frontal headache, pain in the neck and back, chilly sensations and weakness, and a temperature running between 37.8 and 38.2 C. (100.04 and 100.76 F.); on the fifth day the symptoms subsided except for some weakness and also some intermittent precordial pain and irregularity of the pulse. On the tenth day he swabbed his throat and nose thoroughly with a filtrate of an emulsion of influenza sputum in salt solution, but this was not followed by the development of any symptoms.

---

[1] Nicolle, Charles, and Le Bailly, Charles: Quelques notions expérimentales sur le virus de la grippe, Compt. rend. Acad. d. sc., 1918, **167**, 607.

[2] Dugarric de la Rivière, R.: La grippe, est-elle une maladie à virus filtrans? Compt. rend. Acad. d. sc., 1918, **167**, 606.

The results of the work of these French investigators are, of course, most interesting and suggestive as indicating that this disease is caused by a filtrable virus. However, in view of the small number of experiments and the fact that the spontaneous development of influenza cannot be entirely excluded, they can hardly be accepted as demonstrating conclusively that influenza is caused by a filtrable virus. The reports of further investigations must be awaited.

GOITER PROPHYLAXIS IN SCHOOLGIRLS

The high incidence of simple goiter in various regions of the United States as well as in other parts of the world is beginning to be appreciated. Since goiter develops particularly during the adolescent period, the most valuable and accurate data as to its occurrence can probably be obtained from the examination of the public school population. Only beginnings have been undertaken in this direction; but the widespread employment of school physicians and the introduction of modern methods of school medical inspection and personal prophylaxis will make a vigorous attack on the goiter problem more promising in the near future. In a complete census of the condition of the thyroid gland in the girls from the fifth to the twelfth grades of the school population of a large community in the Great Lakes goiter district, it was found that 1,688, or 43.59 per cent., had normal thyroids; 2,184, or 56.41 per cent., had enlarged thyroids, and 594, or 13.4 per cent., had well-defined, persistent thyroglossal stalks. The community lies near the southern edge of the goiter district, and it is suggested that communities near the lakes would show a higher incidence. This demonstration of the extent of goiter occurrence, the outcome of a study made under the auspices of the Committee on Therapeutic Research of the Council on Pharmacy and Chemistry of the American Medical Association by Marine and Kimball[1] of Cleveland, ought to pave the way for successful therapy on a large scale.

If we accept the dictum of the Cleveland investigators that "simple goiter is probably the easiest of all known diseases to prevent," it follows that efforts to undertake prophylactic work should be initiated without delay. To offset the possible hesitation of the want-to-be-shown members of the profession, an actual therapeutic demonstration on a large scale has already been carried to a point at which the results achieved are both striking and convincing.[2] For the prophylactic treatment, sodium iodid was selected on the grounds of economy and ease of administration. The thyroid gland has an extraordinary affinity for iodin; and an exceedingly small amount of this element suffices, as numerous experiments have clearly demonstrated, to protect a gland against hyperplasia even under conditions in which such a development would otherwise be a characteristic compensatory response to thyroidal deficiencies. In their large project at Akron, Ohio, where Marine and Kimball made the survey of the incidence and the types of thyroid enlargement in the schoolgirls from the fifth to the twelfth grades, inclusive, the dose of iodid selected was small in comparison with customary iodin therapy, but large in contrast with what animal experiments suggest as needful. The evidence indicates that from 25 to 30 mg. "saturate" the normal thyroid of from 20 to 25 gm. (⅔ to 1 ounce). Marine and Kimball arbitrarily selected the employment of 2 gm. of sodium iodid, given in 0.2 gm. doses each school day, for each pupil in the fifth, sixth, seventh and eighth grades; and 4 gm. in 0.4 gm. doses each school day for each pupil in the ninth, tenth, eleventh and twelfth grades. These amounts of the drug were given in May, 1917, at the schools by the teachers or nurses.

A complete reexamination of all girls from the fifth to the twelfth grades was made six months later. The summarized results[2] show that not a single pupil in whom the thyroid was normal at first and who took iodin showed any enlargement, while of those not taking iodin, 26 per cent. showed definitely enlarged thyroids, and some, moderately large goiters. Even more than a prophylactic action is shown in the results: Just one third of the goiters marked "small goiters" disappeared; and one third of those marked "moderate goiters" showed a decrease of 2 cm. or more. Accordingly, the investigators properly remark, a distinct therapeutic effect is clearly demonstrated.

These statistical findings are the more conclusive because they represent not dozens but hundreds of carefully examined cases. More than a thousand girls took the full treatment, the latter being restricted for the present to this sex because during the adolescent period simple goiter occurs about six times more frequently in girls than in boys. The iodid rash prophesied by some critics failed to materialize in any noticeable way in more than five girls, in whom it was transitory and uneventful, promptly clearing up when the treatment was stopped. The investigators also now give assurance that there is no danger of producing a toxic condition like exophthalmic goiter. Not a single symptom of this alleged danger from the use of iodids was encountered. Nor was anything different to be expected; for, as Marine and Kimball remind us, the risk of inducing manifestations of exophthalmic goiter from the use of iodin in physiologic doses is exceedingly small, even in those cases in which there were large hyperplastic thyroids, that is, the kind of thyroid enlargement that would permit of the most rapid formation and excretion of the iodin-containing hormone. The extent to which iodids are used in general medicine and surgery and the rarity of the development of signs of exophthalmic goiter is the best index of the danger. Iodin is usually employed in immensely large doses; from 0.2 to 0.4 gm. of sodium iodid daily for two weeks would offer a great excess over the amounts necessary to saturate even the largest thyroids, and probably much smaller amounts would suffice in man, as it has been proved to do in the lower animals. The Akron experiment is being continued on an even larger scale. It should serve both as a model and as a stimulus for comparable efforts elsewhere.

ANTISCORBUTICS

The justification for a careful consideration of the subject of antiscorbutic agents is presented by the recent studies of experimental scurvy.[1] McCollum[2] remarked recently in a symposium on diseases due to deficiencies in nutrition:

> Recovery from scurvy following a change of diet, or an improvement of the bacteriologic condition of the food, or following the administration of substances having diuretic properties, may be more satisfactorily explained in other ways than by the assumption that such changes in the dietary regimen produce their effects because of the introduction of a hypothetic antiscorbutic substance. It is necessary, henceforth, that those who discuss the etiology of scurvy should take into consideration the results of recent researches in nutrition with simplified diets. Whoever would seek to establish the validity of the theory of the existence of a specific antiscorbutic substance should first furnish new explanations for the experimental results that are not in harmony with the antiscorbutic theory, rather than present new experiments that harmonize with this most attractive hypothesis.

Nevertheless, at the present moment—and who can foretell the future in these days of enormous progress in the knowledge of the science of nutrition—it seems clear from the available evidence[1] that certain species at least may show scorbutic symptoms despite the fact that they are on a regimen that seems to meet the requirements of present-day investigators. For example, both Cohen and Mendel[3] at Yale, and Hess and Unger[4] at the Department of Health in New York, have recently demonstrated the genesis of disease in guinea-pigs abundantly supplied with food that contained admittedly good protein, a liberal variety of inorganic salts, supplements of sources of the recognized "fat-soluble" and "water-soluble" vitamins, and the roughage to regulate the movement of the bowels.

Small additions of raw milk do not prevent the onset of scurvy. Larger quantities cause the symptoms to disappear. But the long recognized source of antiscorbutics is found in the fresh fruits and vegetables. Precisely how their potency manifests itself need not concern us here. The fact that scurvy has not only a civil but also a military significance at this time is of itself enough occasion to search for dietary possibilities that will assist in averting or curing the disease. When we are told by competent observers that prunes and bananas are not antiscorbutic, whereas oranges and cabbages are markedly effective, it becomes clear that no broad generalizations can be made, nor can haphazard choice be expected to lead to antiscorbutic dietary success. Assuredly there is need, as Hess remarks, not only of an exact inventory of antiscorbutic foodstuffs, such as has been recently undertaken by the Lister Institute in London,[5] but also of efforts directed to enlarge their number.

Even this plan now seems inadequate to meet the current situation. The movement toward conservation of foods, particularly exemplified in the drying and preserving of fruits and vegetables, is likely to be an extensive one. Do these foods thus conserved retain their antiscorbutic potency? According to Hess and Unger,[4] commercial dehydrated carrots retain practically no antiscorbutic virtues. This statement is in accord with the findings of various European experimenters. Cohen and Mendel have modified the general statement by indicating that cabbage, which is markedly antiscorbutic, apparently may be dried so as to retain some, at least, of its potency. Even orange juice, the antiscorbutic *par excellence,* has been found to lose some of its power when allowed to age for some months in a refrigerator; and the "artificial orange juice" of salts, sugar and citric acid, as proposed by McCollum, is said to fail to protect against scurvy.[4] From a practical standpoint, in the face of high prices for foods, it seems worth while to reemphasize Hess' discovery that orange peel possesses marked antiscorbutic potency and withstands desiccation remarkably well, retaining considerable of this power after being dried for three months.

Some day, we may confidently expect to discover some order in the apparent chaos of this subject. Meanwhile the safety of large groups of the human race demands accurate information on matters that seem to offer at best crudely empiric knowledge. To say that any food lacks antiscorbutic potency is not to condemn it or exclude it from the dietary. The foremost warning is, not to make our rations too exclusive in character, not to depend as yet solely on dried or preserved products, but rather to include some fresh foods as far as circumstances permit—until the experts either improve the methods of conservation so as to retain antiscorbutic potency in them or give us a guide to physiologic safey in our dietary choices.

Current Comment

LEST YOU FORGET

Last week opportunity was given to Fellows of the Association and to subscribers to remit annual dues and subscription, using a blue slip inserted in THE JOURNAL. Many, desirous to aid the Association in effecting a great saving in the sending of regular bills, have already responded. It is hoped that many more will require no further reminder to act. Lest you forget we say it yet: Use the Blue Slip.

THE NUTRITIVE VALUE OF THE BANANA

A prominent organization for conserving the health of the less well-to-do classes has adopted the dictum, "Spend not more for meat and eggs together than for vegetables and fruits."[1] The part that meat and eggs play in the dietary is well known. They offer proteins and fats in acceptable form, and the egg furnishes a quota of vitamins in addition. The grouping of vegetables and fruits in a promiscuous way may tend to obscure the great differences that exist between the different, highly unlike classes of such plant products. Roots, tubers, stalks, green leaves and fruits proper are too diverse in their botanic morphology as well as their chemical make-up to receive indiscriminate consideration in the eyes of the dietitian. All of the products mentioned may provide pleasant and varied flavors and may give desirable texture or bulk to the diet. Some of them undoubtedly furnish vitamins, though it must be admitted that our knowledge of the distribution of these factors is still most fragmentary. As a rule, however, they supply acceptable carbohydrates in the form of starch and sugars. Thanks to the more recent methods of physiologic investigation of dietary values, a new physiology of foods is being created. This has emancipated the student of nutrition from the generalities of former days and enabled him to form more useful conceptions of the specific values of individual products. Numerous instances of what this mode of examination may reveal have been detailed from time to time in THE JOURNAL. An added illustration is afforded by the recent studies of the nutritive value of the banana by Sugiura and Benedict.[2] They refute the assumption that a population can subsist exclusively on bananas as food.[3] These fruits are now definitely demonstrated to be deficient in protein and the water-soluble accessory as a food for the growth and maintenance of experimental animals. The lacking factors must be supplied before a complete dietary results. These shortcomings need not detract, however, from the other nutrient virtue of this sterile fruit.[4] It remains a delicious and digestible sugary food even if it lacks all the virtues of an ideal product like milk.

THE AWE-INSPIRING UNKNOWN

In few places does familiarity breed greater contempt than in the field of therapeutics. None know this better than the exploiters of nostrums—whether for physicians' prescription or for direct consumption by the public. This thought is inspired by reading the label of a proprietary brand of clay poultice which informs the world that the base of this marvel is "composed of the finest anhydrous and levigated argillaceous mineral." It would be fatal, commercially speaking of course, to tell the public what it could, but probably will not, easily find out by looking in the dictionary, that this specimen of exuberant verbosity simply means that the base of the product is nothing more miraculous than dried and finely powdered clay. But how much more sonorous, how much more awe-inspiring, how much more suggestive of incantations and the witch-caldron: "anhydrous and levigated argillaceous mineral." One cannot help feeling that "Prof." Samuels, the shrewd and genial quack who dispensed a pinch each of salt and sugar in hydrant water ($5.00 for 2 oz.), made a mistake in not taking the public into his confidence ("patent medicinally" speaking), by telling them the composition of his panacea. With perfect truth he might have said, for instance:

> "My preparation is composed of minimal quantities of a member of the disaccharid carbohydrates, derived from the hexoses and capable of yielding two hexose molecules by hydrolysis, having as a general formula $C_{12}H_{22}O_{11}$, and crystalizing in monoclinic prisms, together with an interesting chemical combination of natrium and chlorin, which, in its natural state, forms anhydrous, cubical or octahedral white crystals. These are dissolved in a colorless, limpid fluid compounded of hydrogen and oxygen."

Thus might Samuels, taking a leaf out of the notebook of the clay-poultice exploiters, have avoided the charge that he was unwilling to let the public know what he was selling. He might, conceivably, have impressed physicians of a certain type! A seeming frankness is the order of the day in advertising "patent medicines"; does not the public know, full well, that the base of the wonder-working poultice is "anhydrous and levigated argillaceous mineral"? What more can it ask?

BRAIN ANALYSIS IN PATHOLOGY

The chemical pathology of the brain can lay claim to few facts that have been established by adequate data from suitable material. Even in the case of the normal brain, the number of analytic chemical studies conducted in recent years with approved methods has been woefully small. Hence the basis for comparisons of the conditions found in health and disease remains for the most part to be more firmly established. Through the untimely death of Waldemar Koch, at Chicago a few years ago, science lost one of its most promising workers in this domain. Recognizing the paucity of contributions to our knowledge of the chemical composition of the human brain, we need not hesitate to evaluate at some worth the contributions that the more lowly animals may offer. Koch and Riddle have made a chemical study of the brains of pigeons having a functional abnormality recognized as a lack of control of the voluntary movements.[1] The derangement, which usually persists until death, first appeared in these birds under conditions known to lead to weakness in the offspring. The disorder is exhibited in all degrees and has been inherited undiminished to the fifth generation. Usually it is shown from the earliest age, and is probably present throughout the whole development of the bird. Without giving the minutiae of the elaborate analyses made, it has been found that the brains of the ataxic individuals differed clearly from those of normal pigeons. The results of the analyses of the affected brains are interpreted as suggesting a chemical underdifferentiation or immaturity of these brains. The brains of affected birds of approximately mature age are chemically more like the brain at earlier stages of development. Although few opportunities for comparison are as yet available, the chemical variations from the normal as observed in the ataxic pigeon brains and in human amaurotic dementia are apparently alike in kind.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending December 20, there were in the Medical Corps 30,047 officers, a decrease of 998 since the previous week. This personnel includes four major-generals, five brigadier-generals, 221 colonels, 509 lieutenant-colonels, 2,454 majors, 9,771 captains and 17,083 lieutenants. There were in active service 29,232, a decrease of 990 since the previous week. Discharges to date include 4,240 officers.

The Association of the Medical Veterans of the World War

To Commissioned Officers in the Medical Corps of the United States Army, United States Navy, United States Public Health Service, and Medical Members of the Boards of the Selective Service System:

There has been incorporated and officered, the Association of Medical Veterans of the World War, with headquarters in Washington, D. C.

All physicians and surgeons commissioned in the Medical Reserve Corps, or Medical Corps of the United States Army, United States Navy, United States Public Health Service, medical members and medical examiners of Local, Medical Advisory and District Boards officially appointed by the President, or by the governors of states, may become active members by signing the proper application and paying the nominal sum of $1.

The Association of Medical Veterans of the World War is for the purpose of perpetuating fellowships formed in the military service of the United States, 1914 to 1918; promoting reunions of medical veterans; providing a common point of contact for organizations of medical men already founded or to be later instituted, who took official part in winning the world war; for advancing medical science among its members, and for protecting those in need, through declining years.

It is expected that this organization may become the medium of association with foreign societies of medical war veterans, to the end that the medical profession of nations may continue to be allied, in harmony with the governments that made common cause and secured a common victory.

Special associations of medical war veterans, with membership restricted to states, to the selective service, specialists in medicine, overseas service, etc., are invited to elect delegates to represent them in the house of representatives, to which the government of the Medical Veterans of the World War will be entrusted, through the board of directors, to be elected by this house of representatives.

The first convention of the Medical Veterans of the World War, to be held in Atlantic City, N. J., during the second week in June, 1919, will be the Victory Meeting, at which the affairs of the association will be placed in the hands of its officers, to be elected at that time.

Physicians who are qualified by service in either of the Medical Corps of United States government or because of having served by appointment as a member of one of the boards under the selective service system, are requested to submit applications for membership, stating the branch of service in which they have been engaged, together with their membership fee ($1), to the secretary of the association, Col. Frederick F. Russell, care of the Office of the Surgeon-General of the Army, Washington, D. C.

Frederick F. Russell, M.D., Washington, D. C.
Colonel, M. C., U. S. Army.

Weekly Bulletin A. E. F.

Nov. 25, 1918

This bulletin begins with a discussion of the current epidemic of respiratory diseases with extracts from newspapers showing recrudescences occurring in Germany, Hungary, Holland, Switzerland and Portugal. In Portugal the epidemic seemed particularly virulent, many patients dying within forty-eight hours. A statement by the Director-General of Sanitation indicates that some 25,000 people had already died, and that an average of 300 daily were dying in Lisbon. The height of the epidemic in the American Expeditionary Forces was reached in the week ending October 27. From June 15 to November 8 there had been 78,713 cases of influenza and 11,165 cases of pneumonia complicating influenza with 191 deaths attributed directly to influenza and 4,754 deaths from pneumonia. The mortality from influenza, it is stated, cannot be figured with any degree of accuracy on account of the large number of pneumonia cases reported as secondary to influenza. The final paragraph on this subject states:

> Field Hospital No. 366, 92d Division, used sheet cubicle system about beds and masks for patients and attendants so consistently and thoroughly that none of the attendants, doctors, or orderlies acquired influenza or pneumonia although the wards were often full of both diseases.

Other paragraphs follow:

> All the communicable diseases have shown a reduction in the past week except measles and meningitis. The increase in measles has been almost wholly confined to the camps and depots where replacement troops have been assembled from the Base Ports for distribution in the Armies.
>
> The meningitis is widely scattered, only a few of the hospital groups in the Advance Section having reported more than one case in the same unit.
>
> The weekly case rate for influenza has fallen from 601 per 100,000 in the week ending October 25th to 261 per 100,000 in the week ending November 15th.
>
> The weekly case rate per 100,000 for pneumonia in the week ending October 25th has fallen from 109 to 42.5 in the week ending November 15.

Dec. 2, 1918

This bulletin first points out the inaccuracy of many reports as to the cause of death given by pathologists in connection with the Army. Paragraphs are devoted to a small outbreak of typhoid from untreated water at Autreville, to the management of diphtheria at a hospital center, to a memorandum on lipovaccines against pneumonia issued by the Surgeon-General's Office, to organization in the handling of venereal diseases, and to the final weekly review.

> There has been an increase in diphtheria, scarlet fever and meningitis; diphtheria showing an increase in several hospital centers. The meningitis increase is almost wholly confined to the advanced zone. These increases do not show any evidence of local epidemics, the cases for the most part being widely scattered.
>
> The monthly period, however, shows a marked reduction in dysentery and meningitis, a slight reduction in measles, and a marked increase in typhoid. Diphtheria slightly increased, with measles and scarlet fever showing little change.
>
> The improvement in the influenza and pneumonia situation continues. For the week ending November 22, 1,552 cases of influenza reported against 4,862 the week previous, and 407 of pneumonia against 793 the week previous.

To Camp Gordon, Ga., with the board examining the troops for cardiovascular diseases, from Fort Oglethorpe, Capt. C. C. ORR, Asheville.

To Camp Hancock, Ga., from Camp Greene, Lieut. L. O. GIBSON, Statesville.

To Camp Shelby, Miss., base hospital, from Fort Oglethorpe, Capt. J. J. BAREFOOT, Graham.

To Plattsburg Barracks, N. Y., from Camp Jackson, Capt. M. C. PALMER, Tryon.

Ohio

To Azalea, N. C., from Camp Crane, *Lieut H. H. LOWE*, Leesburg; from Fort Oglethorpe, Lieut. A. M. ROSENBLUM, Youngstown.

To Camp Abraham Eustis, Va., as orthopedic surgeon, from Fort Oglethorpe, Capt. L. B. ZINTSMASTER, Massillon; Lieut. N. J. SEYBOLD, Toledo.

To Camp Dodge, Iowa, with the board examining the troops for cardiovascular diseases, from Fort Oglethorpe, Capt. R. H. QUICK, Toledo.

To Camp Grant, Ill., base hospital, from Fort Oglethorpe, Lieuts. H. P. TIMBERLAKE, Cleveland; H. K. BECKWITH, Toledo.

To Camp Hancock, Ga., from Camp Greene, Lieuts. B. B. BRIM, J. J. SWEENEY, Toledo.

To Camp Sheridan, Ala., with the board examining the troops for cardiovascular diseases, from Fort Oglethorpe, Capt. D. W. PHILO, Fremont.

To Cape May, N. J., from Camp Crane, Capt. M. E. BLAHD, Cleveland.

To Carlisle, Pa., from Ann Arbor, Capt. W. F. MAXWELL, Toledo.

To Denver, Colo., from Fort Riley, Lieut. R. R. KERKOW, Hicksville.

To Fort Leavenworth, Kan., from Ann Arbor, Lieut. L. A. LURIE, Cincinnati; from Fort Oglethorpe, Lieut. W. H. VORBAU, Lima.

To Fort McHenry, Md., for instruction, from Fort Oglethorpe, Lieut. F. F. KRAMER, Cincinnati.

To Fort Sam Houston, Texas, base hospital, from Ann Arbor, Lieut. P. G. TAIT, Toledo.

To Fort Snelling, Minn., from Army Medical School, Capt. E. A. KLEIN, Norwood.

To Hoboken, N. J., from Fort Oglethorpe, Lieut. W. P. ULTES, Springfield.

To Newport News, Va., from Fort Oglethorpe, Lieut. J. W. JOLLEY, Morral.

To Richmond, Va., from Fort Oglethorpe, Lieut. W. J. FRANCIS, Kalida.

To Walter Reed General Hospital, D. C., from Plattsburg Barracks, Lieut. A. E. KISER, Cincinnati.

To Washington, D. C., St. Elizabeth's Hospital, from Ann Arbor, Lieut. J. H. BERRY, Lima.

The following orders have been revoked: *To Camp Crane, Pa.,* from Hoboken, Lieut. D. W. FELLERS, Bloomville. *To Fort Dupont, Del.,* from Camp Holabird, Lieut. R. A. ELLIOTT, Alger.

Oklahoma

To Denver, Colo., from Fort Riley, Lieut. H. M. NICHOLSON, Muskogee.

To Fort Benjamin Harrison, Ind., from Fort Oglethorpe, Lieut. F. H. CLARK, El Reno.

Oregon

To Fort Leavenworth, Kan., from Camp Lewis, Lieut. D. R. ROSS, Salem.

The following orders have been revoked: *To Camp Lewis, Wash.,* base hospital, for instruction, from Camp Crane, Lieut. G. L. BOYDEN, Pendleton. *To Camp Wadsworth, S. C.,* base hospital, from Camp Crane, Capt. C. E. SEARS, Portland.

Pennsylvania

To Arcadia, Fla., Carlstrom Field, from Mineola, Capt. S. H. HORNE, Philadelphia.

To Baltimore, Md., from Plattsburg Barracks, Capt. C. C. WHOLEY, Pittsburgh.

To Camp Gordon, Ga., with the board examining the command for nervous and mental diseases, from Fort Oglethorpe, Lieut. W. C. CHANEY, Philadelphia.

To Camp Grant, Ill., base hospital, from Fort Oglethorpe, Lieut. G. C. GLENN, State College.

To Camp Hancock, Ga., from Camp Greene, Lieuts. F. J. CONAHON, Morea Colliery; J. M. HIGGINS, Sayre.

To Camp Henry Knox, and to Camp Zachary Taylor, Ky., with the board examining the troops for cardiovascular diseases, from Fort Oglethorpe, Capt. C. FALKOWSKY, Jr., Scranton.

To Camp Jackson, S. C., base hospital, from Camp Crane, Lieut. J. M. FLEMING, Blairs Mills; from Camp Travis, Capt. G. P. PILLING, Jr., Philadelphia.

To Camp Logan, Texas, base hospital, from Camp Dodge, Lieut. W. E. RAMSEY, Philadelphia.

To Camp Sherman, Ohio, base hospital, from Fort Oglethorpe, Lieut. H. W. JONES, Philadelphia.

To Camp Upton, N. Y., base hospital, from Fort Oglethorpe, Lieuts. P. A. LONERGAN, Dickson City; A. LEVY, Philadelphia.

To Camp Zachary Taylor, Ky., base hospital, for instruction, from Fort Oglethorpe, Capt. H. D. JORDAN, Allentown.

To Cape May, N. J., from Fort Oglethorpe, Lieut. J. P. ROTH, Ashland.

To Colonia, N. J., from Camp Crane Capt. R. J. BEHAN Pittsburgh; from Fort Oglethorpe, Lieut. E. N. FOSTER, Pittsburgh.

To Fort McHenry Md., from New York, Lieut. C. A. LEY, Pittsburgh.

To Fort Sheridan, Ill., from Fort Oglethorpe, Lieut. D. J. MORTON, [illegible] nstruction, from Fort Oglethorpe, Capt. H. P. LEO- [illegible] Taliaferro Field, as assistant to flight surgeon, from Mineola, Capt. C. W. JENNINGS, Pittsburgh.

To Hoboken, N. J., from Fort Oglethorpe, Lieut. T. A. MONOHAN, Shenandoah.

To Houston, Texas, Ellington Field, from Mineola, Capt. W. MARSHALL, Pittsburgh.

To Pittsburgh, Pa., from Fort Oglethorpe, Lieut. J. A. MALONEY, Philadelphia.

To report to the Commanding General, Northeastern Department, from Boston, Capt. R. P. SMITH, Philadelphia; Lieut. S. H. KELLER, Pittsburgh; from Camp Devens, Capt. I. E. FREYMAN, Weatherly.

To Walter Reed General Hospital, D. C., from Camp Crane, Lieut. E. L. WHISTLER, Carlisle.

The following orders have been revoked: *To Hoboken, N. J.,* from Fort Hancock, Lieut. J. M. MONAGHAN, Minersville. *To Richmond, Va.,* for instruction, from Fort Oglethorpe, Lieut. R. S. HINCHMAN, McKeesport. *To West Baden, Ind.,* from Camp Crane, Lieut. B. FULTON, Pittsburgh.

Philippine Islands

To San Francisco, Calif., from Philippine Islands, Major E. T. B. WEIDNER.

Rhode Island

To Cooperstown, N. Y., from Mineola, Capt. A. W. STEVENSON, Newport.

To Rochester, Minn., Mayo Clinic, for instruction, and on completion to *Walter Reed General Hospital,* from Walter Reed General Hospital, Lieut. W. J. O'KEEFE, Providence.

South Carolina

To Camp Lee, Va., from Camp Greene, Capt. E. F. ROSS, Anderson.

Tennessee

To Azalea, N. C., from Fort Oglethorpe, Lieuts. C. G. GRIFFIN, Nashville; E. A. GILBERT, St. Elmo.

To Camp Hancock, Ga., as tuberculosis examiner, from Waynesville, Capt. J. O. WOODS, Newport. Base hospital, from Fort Oglethorpe, Capt. R. W. DAKE, Nashville.

To Camp Jackson, S. C., base hospital, from Fort Oglethorpe, Lieut. H. S. SHOULDERS, Springfield.

To Camp Joseph E. Johnston, Fla., base hospital, from Fort Oglethorpe, Lieut. H. Q. FLETCHER, Chattanooga.

To Denver, Colo., from Fort Oglethorpe, Lieut. H. P. CONLEY, Memphis.

To Fort Benjamin Harrison, Ind., from Fort Oglethorpe, Lieut. T. D. CLOYD, Mosheim.

To Fort Leavenworth, Kan., from Columbus Barracks, Capt. J. P. SCHOLL, Nashville; from Fort Oglethorpe, Capt. G. A. HATCHER, Nashville.

To Hoboken, N. J., from Camp Crane, Capt. J. H. KING, Chestnut Mound.

To Lake Charles, La., Gerstner Field, as flight surgeon, from Mineola, Capt. G. E. CAMPBELL, Elizabethtown.

To Walter Reed General Hospital, D. C., from Camp Custer, Lieut. H. O. ANDERSON, Williamsport.

The following orders have been revoked: *To Fort Riley,* base hospital, from Fort Oglethorpe, Capt. O. J. PORTER, Columbia. *To report to the Commanding General,* Southeastern Department, from Fort Logan, Lieut. W. H. NILES, Tellico Plains.

Texas

To Camp Bowie, Texas, base hospital, from Fort Oglethorpe, Lieut. A. C. ROGERS, Odell.

To Camp Hancock, Ga., from Camp Greene, Lieut. T. M. JARMON, Terrell.

To Camp Henry Knox and *to Camp Zachary Taylor, Ky.,* with the board examining the troops for cardiovascular diseases, from Fort Oglethorpe, Major E. V. DePEW, San Antonio.

To Camp MacArthur, Texas, base hospital, from Fort Oglethorpe, Lieut. W. S. LORIMER, Handley.

To Camp Shelby, Miss., for instruction, from Camp Crane, Major W. M. WOLF, San Antonio.

To Camp Sherman, Ohio, base hospital, from Fort Oglethorpe, Capt. W. B. HUNTER, Fort Bliss.

To Dallas, Texas, from San Antonio, Lieut. D. A. MOHLER, Dallas.

To Fort McHenry, Md., for instruction, from Fort Oglethorpe, Capt. M. W. SHERWOOD, Temple.

To Fort Sill, Okla., base hospital, from Fort Oglethorpe, Capt. J. H. BRICE, Lamesa.

The following orders have been revoked: *To Camp Abraham Eustis, Va.,* from Camp Custer, Lieut. L. PENROD, Gonzales. *To Dallas, Texas,* from San Antonio, Lieut. R. M. MILNER, Yoakum. *To Camp Shelby, Miss.,* for instruction, from Camp Crane, Major W. M. WOLF, San Antonio.

Utah

To Camp Hancock, Ga., as tuberculosis examiner, from Fort Oglethorpe, Lieut. G. W. GOINS, Toolle.

Virginia

To Camp Devens, Mass., base hospital, from New Haven, Lieut. G. A. L. KOLMER, Salem.

To Camp Hancock, Ga., from Camp Lee, Capt. E. W. YOUNG, McKenney.

To Fort McHenry, Md., for instruction, from Fort Oglethorpe, Capt. J. M. ROBINSON, Danville.

To Hoboken, N. J., from Fort Oglethorpe, Lieut. J. L. HANKINS, Fordwick.

To report to the Commanding General, Northeastern Department, from Boston, Lieut. J. A. LAFFERTY, McKees Rocks.

Washington

To Fort Leavensworth, Kan., from Camp Lewis, Major A. P. CALHOUN, Seattle; from Fort Oglethorpe, Lieut. J. HEHIR, Sedro-Wooley.

To Fort George Wright, Wash., Capt. A. A. MATTHEWS, Spokane.

To San Diego, Calif., Rockwell Field, as assistant to flight surgeon, from Mineola, Capt. G. W. BEELER, Seattle.

West Virginia

To Azalea, N. C., from Camp Devens, Capt. G. H. BARKSDALE, Charleston.

To Boston, Mass., for instruction, from Camp Beauregard, Capt. J. C. SCHULZ, Huntington.

To Camp Crane, Pa., from Hoboken, Lieut. J. C. LAWSON, Logan.

To Camp Hancock, Ga., base hospital, from Fort Oglethorpe, Lieut. W. S. Crawford, Follansbee.

To Camp Meade, Md., from Camp Gordon, Major E. DAVIS, Charleston.

To Edgewood Arsenal, Md., as orthopedic surgeon, from Fort Oglethorpe, Lieut. E. B. HENSON, Charleston.

To Fort Leavenworth, Kan., from Camp Lee, Lieut. R. DODSON, Spencer.

Wisconsin

To Camp Gordon, Ga., with the board examining the troops for cardiovascular diseases, from Fort Oglethorpe, Lieut. R. E. FITZGERALD, Cudahy.

To Camp Shermon, Ohio, base hospital from *Boston,* Capt. J. W. POWERS, Burlington.

To Camp Wheeler, Ga., base hospital, from Camp Crane, Lieut. O. E. ISHMAEL, Mount Horeb.

To Fort Sheridan, Ill., from Fort Oglethorpe, Lieut. P. C. HODGES, Madison.

To Fort Snelling, Minn., from Fort Oglethorpe, Lieut. W. G. SEXTON, Marshfield.

To West Point, Miss., Payne Field, as flight surgeon, from Mineola, Major C. W. ANDREWS, Waupaca.

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Asst. Surg. M. C. EDMUNDS, proceed to the Reedy Island Quarantine Station for temporary duty.

Asst. Surg. M. F. HARALSON, proceed to Florence, Ala., for inspection of sanitary work now being carried on by the Service.

Acting Asst. Surg. J. J. DURRETT, proceed to Washington for conference relative to construction of a sewage disposal plant at Newport News, Va.

Acting Asst. Surg. I. R. GORROV, proceed to Washington, D. C., for conference relative to influenza work in the state of Ohio.

Sanitary Engr. C. N. HARRUB, relieved at Jacksonville, Fla., proceed to Columbus, Ga., for duty in extracantonment sanitation.

Scient. Asst. SEVERANCE BURRAGE, relieved at New London, Conn., proceed to Ayre, Mass., for duty in extracantonment sanitation.

Scient. Asst. WALLACE PURRINGTON, relieved at New London, Conn., proceed to Portsmouth, N. H., for duty in extracantonment sanitation.

Chief Sanitary Insp. W. H. GILLETTE, relieved at Jacksonville, Fla., proceed to Atlanta, Ga., for duty in extracantonment sanitation.

Chief Sanitary Insp. JOHN F. GORDON, relieved at Portsmouth, N. H., proceed to Raleigh, N. C., for duty in extracantonment sanitation.

Chief Sanitary Insp. J. L. JACKSON, relieved at Jacksonville, Fla., proceed to Columbus, Ga., for duty in extracantonment sanitation.

Chief Sanitary Insp. W. J. JOYCE, relieved at New London, Conn., proceed to Raleigh, N. C., for duty in extracantonment sanitation.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Personal.—Dr. Frank H. Pritchard, Colton, who has been seriously ill with heart disease following influenza, is reported to be convalescent.——Dr. James B. Cutter, Watsonville, has been appointed executive surgeon at the Southern Pacific Hospital, San Francisco.——Dr. Ernest Crutcher, Los Angeles, has been appointed special representative of the state board of health to take charge of the influenza situation at Blythe in the Imperial Valley.

County Medical Society Protests Discharge of Reserve Officers.—The San Diego County Medical Society has protested to the adjutant-general of the state of California regarding the manner in which physicians serving with the Medical Corps are being discharged from service on telegraphic orders. The protest states that:

> Whereas, medical officers who gave up good homes and lucrative practices to enter the medical reserve corps are being discharged from the service on telegraphic orders from Washington without proper notice or customary privileges due an officer.
>
> This council hereby protests against this manner of discharge and asks that Adjutant-General Borree communicate with the proper authorities in Washington and have such irregularities corrected.

ILLINOIS

Disqualified Physician Fined.—Dr. Samuel R. Harwood of East St. Louis, whose license to practice medicine and surgery in the state of Illinois was revoked some three months ago, has promised the authorities of St. Clair County that he will leave the state if they will permit him to plead guilty to one of the eight indictments returned against him by the grand jury of that county and pay a fine of $500 for obtaining money under false pretenses. His offer has been accepted by the state's attorney. The eight indictments returned against Harwood for practicing a confidence game and obtaining money under false pretenses were returned by the grand jury of St. Clair County immediately following the revocation of his license.

Licenses Revoked.—At a meeting of the Department of Registration and Education of the State of Illinois, held in Chicago, Dec. 9, 1918, the license of Franklin J. Oshay, Ladd, who holds license No. 10724, issued by the state board of health, Nov. 15, 1892, to practice medicine and surgery in all their branches in the state of Illinois, was revoked. The charges against Dr. Oshay were that he was an habitual drunkard, and was careless in the writing of prescriptions for habit forming drugs. The license of August M. Unger, Chicago, No. 10546, issued by the state board of health, April 7, 1892, was also revoked. He was charged with unprofessional conduct to young women who answered an advertisement for an office girl. He was charged with telling them that under a recently passed state law all office girls working for physicians were required to submit to a physical examination before beginning their work.

MARYLAND

Personal.—It is reported that Brig.-Gens. J. M. T. Finney and W. S. Thayer have been ordered back to the United States from France.——Lieut. J. Galen Skilling, surgeon in the First Battalion, Twenty-Sixth Infantry of the First U. S. Army, formerly from Cumberland, has been reported as missing since November 7.——Health Commissioner John D. Blake has announced the appointment of Dr. Robert G. Lumpkin of Roland Park, as throat inspector for the health department. Dr. Lumpkin succeeds Dr. G. H. Woltereck, who resigned.

Bon Secours Hospital Opened.—The new Bon Secours Hospital in Baltimore, given by Mr. and Mrs. George C. Jenkins to the sisters of that order, was formally opened, December 21, by Cardinal Gibbons who dedicated the building. The new hospital is provided with the latest and most perfect appliances required in hospital service and will enable the sisters to attend surgical operations in their own hospital. Mother Urban, superior of the Bon Secours Convent, is directress and the following medical men of Baltimore are members of the staff: Dr. Thomas R. Brown, Dr. E. B. Freeman, Dr. Charles O'Donovan, and Dr. E. H. Gaither. The surgical staff is composed of Drs. Alexis McGlannan, J. C. Pound, J. K. Seegar, and M. Kahn.

MASSACHUSETTS

Want Physician for Health Commissioner.—At a meeting of the Somerset Medical Society, held December 12, a resolution was adopted recommending a change in the department of health of the city by abolishing the present board of health and establishing in its stead, a graduate in medicine as full-time commissioner of health.

Personal.—Dr. Henry M. Smith, Lee, has been appointed associate medical examiner (coroner) of Berkshire County, to succeed Dr. John J. Hassett, deceased.——Dr. Esther M. E. Sundelof, Boston, has been appointed assistant physician of the City Hospital, roentgen-ray service.——In the case of "Dr." David Wagner, Springfield, who was said to have been found guilty of performing a criminal operation causing the death of Nellie Osham, and sentenced to five years' imprisonment in the state prison at Charlestown, the supreme court has overruled the exceptions, and the authorities have been ordered to arrest Wagner that he may serve his sentence.

NEBRASKA

Action Regarding Influenza.—At a meeting at the state capitol building in Lincoln, Tuesday, December 17, called by the state board of health and presided over by the epidemiologist of the state board, Dr. W. H. Wilson, important action was taken and recommendations made regarding influenza, which had assumed a serious stage throughout the state. The meeting was addressed by the governor and by Dr. W. F. Wild, head of the state board, and a committee was appointed consisting of Dr. Wild, Dr. A. J. Jenison, a member of the state legislature, and Superintendent A. H. Waterhouse of the Omaha public schools, which made the following recommendations: That local health boards be organized as provided by law in all counties, cities and villages where such do not now exist and that all boards enforce all present laws relating to contagious diseases, especially as applied to the present epidemic of influenza, and where such local boards fail to organize or fail to carry out the laws the state board establish a health organization and carry out the laws at the expense of such communities; or if local organizations are unable to cope with the situation that outside help be obtained. Each community is urged to organize a corps of nurses to be trained along practical lines, and complete reporting of cases is enjoined on physicians. Public schools should adopt medical inspection, or, in the absence of that, the teachers are to send home every child showing signs of illness with recommendation to parents to consult a physician. All gatherings for purposes of pleasure and all other unnecessary gatherings should be discontinued. Influenza is to be considered and treated as a quarantinable disease under present state quarantine regulations.

NEW YORK

Personal.—Dr. Arnold A. Samorini, Schenectady, sailed for Italy, December 3, to engage in Red Cross work.

Oral Hygiene Number.—*Health News*, the monthly bulletin of the New York State Department of Health, for November is devoted to the subject of oral hygiene. It contains articles on focal infections, by Meyer L. Rhein; importance of the care of the deciduous teeth, by Frederick A. Keyes; dental hygiene in the Rochester schools, by Harvey J. Burkhart; rational mouth hygiene, by Alfred C. Fones, who presents an illustrated article on how to brush the teeth, and an article on tooth-brush drill, by Albert H. Stevenson, besides editorial and miscellaneous matter.

New York City

Personal.—Charles F. Craig, commanding officer of the Army Laboratory School, at Yale University, New Haven, Conn., who met with a painful elevator accident recently in which he fractured his left leg and dislocated the left patella, is reported to be convalescing.——The Distinguished Service Medal was awarded, October 11, to Col. Louis M. Maus, M. C., U. S. Army, Washington, D. C., retired, by direction of the President, for "Specially meritorious service on the Belle Fourche River, N. D., on Nov. 5, 1877, in that while serving with a detachment suddenly surrounded by an overwhelming force of hostile Sioux Indians he succeeded in extricating the party from the most perilous position."

The Cartwright Prize.—Announcement is made by the Association of the Alumni of the College of Physicians and Surgeons in the City of New York of its biennial Cartwright Prize of $500 to be awarded at Commencement, 1919. Competitive essays must be presented on or before April 1, 1919, typewritten, in English, and accompanied by the usual safeguarding device or motto. They must contain records of original investigations made by the writer. In 1920 the Alumni Prize will be offered, the requirements for which are the same as the Cartwright Prize, excepting that competition is restricted to alumni of the College of Physicians and Surgeons. Essays offered for the Cartwright Prize should be sent to Dr. Henry E. Hale, secretary of the association, at 64 West Fiftieth Street, New York City.

New Diagnostic Hospital.—The New York Diagnostic Society has been organized by Dr. M. Joseph Mandelbaum. In a few days ground will be broken for the establishment of the first hospital of the Diagnostic Society, at 125 West Twenty-Second Street, which will be known as the West Side Branch of the Diagnostic Clinics of the Academy of Diagnosis. The ground and building represent an investment of $250,000. The building will be six stories and basement in height, and will be a model in regard to equipment for diagnostic tests. The society has now a membership of more than 400, and the officers are Dr. M. Joseph Mandelbaum, president; Dr. Monroe Bradford Kunstler, vice president; Lesser B. Grossel, secretary; J. Maxwell Van Dyke, treasurer, and David Frankel, president of the board of lay governors.

GENERAL

Bequests and Donations.—The following bequests and donations have recently been announced:

Episcopal Hospital and Visiting Nurse Society, Philadelphia, each $1,000 by the will of Edmond A. Souder.

Mount Sinai Hospital $10,000, Hebrew Benefit and Orphan Asylum and Montefiore Home each $1,000, and Lenox Hill Hospital, New York City, $500 by the will of Edward Oppenheimer.

New Public Health Officers.—At the annual meeting of the American Public Health Association held in Chicago, December 8 to 11, New Orleans was selected as the next place of meeting and the following officers were elected: president, Lee K. Frankel, New York City; vice presidents, Col. John W. S. McCullough, Toronto, Ont.; Col. Victor C. Vaughan, Ann Arbor, Mich., and Dr. John D. Robertson, Chicago; secretary, A. W. Hedrick, Boston; treasurer, Dr. Guilford H. Sumner, Des Moines, Iowa, and executive committee, Drs. Allan J. McLaughlin, U. S. P. H. S., Washington, D. C.; Charles J. C. O. Hastings, Toronto; Peter H. Bryce, Ottawa; John N. Hurty, Indianapolis, Ind., and William C. Woodward, Boston.

The Work of the Rockefeller Foundation.—George E. Vincent, president of the Rockefeller Foundation, outlined recently the plans of the foundation which included an expedition to Central and South America headed by Major-Gen. William C. Gorgas, formerly Surgeon-General, U. S. Army, to conquer yellow fever which now springs from a few small areas in Central and South America; the operation of a medical university in Peking, China, which is under construction with a cost of $6,000,000, and will be open in 1920, and which will contain eighteen university buildings, forty faculty residences, and a hospital with 200 beds, and a medical school soon to be begun at Shanghai. Subsidies are to be granted to existing missionary hospitals which will be standardized and offer internships for the university. Clinical stations and subhospitals will be established over China. For this work a total expenditure of $10,000,000 is expected, with an additional $250,000 to $500,000 annually for support.

Federal Aid in Rural Health Conditions.—As the result of careful study of rural health conditions, Representative Lever has come to the conclusion that rural health work should be conducted on the same basis as the Lever Extension Plan of promoting agricultural development. He has, therefore, introduced a bill embodying the principle of federal aid and advocates the prompt passage of this as a vital measure of national reconstruction. He calls attention to a bulletin just published by the United States Public Health Service embodying the results of a sanitary survey recently made. In this survey over 50,000 farm houses were visited in fifteen different counties. Of these less than 2 per cent. were equipped for the sanitary disposal of human excreta. More than two-thirds (68 per cent.) used a water supply which was obviously exposed to potentially dangerous contamination from privy contents or from promiscuous deposits of human excreta. In the majority of these the water was also exposed to pollution from stable yards and pig-sties. Only one third of the dwellings were effectively screened during the summer season, to prevent flies, which had free access to nearby deposits of human and other filth, from entering dining rooms and kitchens and contaminating foods intended for human consumption. The bill as introduced, provides an appropriation of $250,000 for the first fiscal year, to be allotted on the half and half plan to the several states, and an appropriation of an additional $250,000 each fiscal year thereafter until a continual appropriation of $1,000,000 is reached.

FOREIGN

Influenza in Switzerland.—The febrile epidemic in Switzerland has kept up so that the annual meetings of the Swiss Neurologic Society and of the Société médicale de la Suisse romande, scheduled to be held in October and November, were postponed *sine die*.

Census of War Disabled.—The prefects throughout Italy have been ordered by the government to collect from every community the data regarding disabled soldiers in their precincts injured in the war. Not only the names and numbers but the pensions paid, the kind and amount of reeducation, the artificial limbs provided, and other details of each individual case are to be compiled and when collected by the prefects are to be sent to the headquarters of the rehabilitation work for the province.

Deaths in the Profession Abroad.—Prof. **P. Dunant** of the University of Geneva, aged 84. He occupied the chair of hygiene from its foundation to his retirement in 1889, and published numerous works on medical statistics, hygiene and demography, and always took a leading part in matters affecting the public health and welfare. He was the brother of Henri Dunant, the founder of the Red Cross.——Dr. **J. Bruchi**, instructor in clinical surgery and operative medicine at Ravenna, aged 45.——Prof. **G. Basile**, assistant to the chair of nose and throat diseases at the University of Catania, and a writer on this specialty.

Committee for Revision of French Codex.—The Commission du Codex has just been appointed. It consists mainly of professors of pharmacy in different universities, with the chief of the pharmacy service for the state hospitals. The director of the system of state higher education is president of the commission, and Professor Roger, dean of the Faculté de médecine of the University of Paris, professor of experimental pathology, is vice president. The list includes also Professors Carnot, Moureu and Desgrez, of the chairs of therapeutics, pharmaceutical chemistry and medical chemistry at the University of Paris, E. Roux, director of the Pasteur Institute, and others to a total of twenty-three.

Agitation for a Minister of Health in France.—The lack of organization and coordination of the various agencies in charge of the public health service has been rendered particularly apparent by the recent events in France, and a concerted movement is now under way to have the public health and hygiene service reorganized as a government cabinet department. Among the forces actively at work to secure this is the Comité national de l'éducation physique et de l'hygiène sociale, the president of which is a member of the lower house from Paris. They appeal to organized industries, societies, associations of any and every kind, to sign and forward to the headquarters of this organization a brief petition which has been widely published, setting forth in half a dozen lines the evils of the present scattering of the public health agencies through so many different government departments, the wasting of effort and the overlooking of important matters between them.

Appeal from the Serbian Red Cross.—The *Policlinico* of November 17 brings an urgent appeal from the president of the Serbian Red Cross for aid to save the population which has been reduced by nearly one half, and which needs donations of clothing, underclothes, cloth, thread, needles, shoes, fresh or conserved foods, tea, sugar, condensed milk, soap, medicines and hospital supplies, besides cash. "Only by prompt donations of the kind," he says, "will it be possible to tide the populace along till the better days to follow the victory, and which the people have so fully and richly deserved. The whole Serbian nation to the depths of its great heart," he adds, "will cherish the deepest gratitude and remembrance of all those who manifest to them in their time of need sentiments of sympathy and altruism." Contributions can be sent to the R. Consolate of Serbia at Salonico or to the R. Console Generale di Serbia at Rome, Italy, via Poli, 25, addressed to the Serbian Red Cross or Croce Rossa Serba.

Two Hundred and Fiftieth Anniversary of Birth of Boerhaave.—Herman Boerhaave was born near Leyden in Holland, Dec. 31, 1668, and the profession in the Netherlands is making great efforts to celebrate the 250th anniversary of this date. In 1709 he was made professor of medicine and botany at the University of Leyden, and students flocked to him from all over Europe while he was remarkably successful as a practitioner of medicine. A story is told that he received a letter from a high official in China addressed merely "Dr. Boerhaave, Europe." The Surgeon-General's Catalogue devotes over two pages to the lists of his works and translations of them into different languages, and biographies and other works about him. He is generally considered to have inaugurated the era of scientific medicine. His "Aphorisms Concerning the Knowledge and Cure of Diseases" and his "Treatise on the Virtue and Energy of Medicines" were his principal works, but he also published several on "Venus Sickness," disease of the eyes, cancer, gallstones, etc. There is to be a festival meeting at the University of Leyden, the scene of his labors, and an exhibition of Boerhaaviana is to be open to the public for a month in the public museum. The National Medical Association and the city of Leyden have cooperated to make the celebration a worthy one. A recent bequest to the city has added materially to its collection of Boerhaaviana.

LONDON LETTER

London, Nov. 26, 1918.

Plans to Check Venereal Disease on Demobilization

The National Council for Combating Venereal Diseases has brought forward proposals for meeting the danger of a large increase when the troops are demobilized. It urges that though great progress has been made in the campaign against venereal diseases, the results are lamentably inadequate, and unless strong measures are taken, there will be grave danger to the public health. There will be about 300,000 men of the army and navy under treatment and infective on demobilization. The incidence of these diseases in the army, where instruction, treatment and discipline combine to reduce infection, is put at only 2 per cent.; in the adult civilian population, where those influences do not obtain, it is estimated at nearly 20 per cent. It is urged that immediate steps must be taken to prevent the spread of disease to wives, families and others. The council makes these recommendations: 1. The Local Government Board should authorize the appointment of whole time venereal officers (a man and a woman) on the staffs of the medical officer of each county or county borough. The present hospital accommodation should be supplemented by special clinics under the supervision of such venereal officers in every town of more than 10,000 inhabitants, and also in the county boroughs, such clinics to be open for continuous and early treatment for both men and women. The military authorities are asked to free immediately as many venereal specialists as the Local Government Board may require, in order that the time before demobilization may be used to establish the clinics to be available early in the new year. 2. Hospitals and medical schools should be requested to arrange special graduate courses for the training of medical women in the modern methods of treatment. A strong appeal is made to medical women to specialize in this subject. 3. Some means should be devised to encourage physicians to diagnose venereal disease in patients and to give early preventive treatment. 4. The army act should be so amended as to enable infective men to be retained pending the completion of treatment. 5. It should be made a statutory obligation for every individual suffering from venereal disease to obtain and to continue treatment until cured. 6. The Local Government Board should consider immediately whether some form of confidential notification of infective cases may be adopted under existing powers, and whether at a later date fresh powers may be obtained from Parliament to secure continuous treatment. 7. The minister of munitions should give instructions that all men and women working for national and controlled firms should receive adequate instruction from responsible physicians. 8. An adequate number of women police should be appointed, and the organization of voluntary women patrols should be increased. 9. Social organizations should increase their efforts to provide recreation under healthy conditions for the youth of the country, especially during the present period of rejoicing.

Simulated Diabetes

A business man, a native of Warsaw, was prosecuted and pleaded guilty of causing a solution of sucrose to be injected into his bladder with view to being rejected on medical examination for the army. He was fined $250. A few other cases of simulated disease with the same object have occurred during the war, but most, if not all, the persons concerned were not English, but foreigners or of foreign extraction.

Sir Hermann Weber

Sir Hermann Weber, M.D., F.R.C.P., has died at his residence in London in his ninety-fifth year. He was a remarkable example not only of longevity but also of excellent health and vigor in old age. He practiced until the age of 80, and in the present year contributed a most interesting article to the *British Medical Journal* on the "Influence of Muscular Exercise on Longevity," which followed out the principles laid down in his essay on "Prolongation of Life." He was able to refer to himself as a marked example of his doctrine. He attributed his vigor at this extreme age to his practice of spending daily two or three hours in the open air and walking as a rule 30 and frequently 40 or 50 miles a week. He was the son of a German father and Italian mother. He was educated at Marburg and afterward at Bonn, where he graduated in 1848. His desire to read Shakespeare in the original led him to study English. He came to England, where he was appointed house physician at the German hospital, and married an English woman in 1854. After a period of study at Guy's hospital he became M.R.C.P., and was elected F.R.C.P., four years later. Among his circle of friends were the eminent physicians of a former generation, Addison, Edmond Parkes, Wilson Fox and Hilton Fagge. He was one of the pioneers of the open air treatment of consumption. Not without protest from the more old-fashioned physicians, he sent his patients to winter in the high valleys of the Engadine. He was himself devoted to mountain climbing, and in the interests of his patients explored the Swiss Tyrolese and Italian Alps. His affection and admiration for Parkes led him to present the College of Physicians with the sum of $15,000 to be awarded every third year for the best essay on some subject connected with tuberculosis. He contributed articles on the treatment of phthisis to Quain's Dictionary and Allbutt's System. His unique knowledge of health resorts was embodied in a volume entitled the "Mineral Waters and Health Resorts of Europe" which was later replaced by "Climatotherapy and Balneotherapy," written in association with his son, Dr. F. Parkes Weber. Throughout the war his sympathies were cordially and wholly with his adopted country, where he had worked for seventy-five years. His younger son and all his grandsons fought in the war, and one was killed at Ypres.

Medicine in War

The fourth annual report of the Medical Research Committee has just been published. This committee owes its origin to Mr. Lloyd George, who founded it in connection with the national health insurance scheme. During the war, the committee has given its advice and services to the army in large measure, and consequently the present is largely a war report. Much of the knowledge gained in war will be available for peace, not only by means of the medical history of the war that the committee is producing, but also by means of published papers and researches. Three facts, the committee thinks, stand out today in the domain of medical research. The first is the awakened interest in scientific work and increased recognition of the value of medical research. The second is the remarkable triumph achieved by the bacteriologist in this war. Thanks to his labors, especially in the direction of preparing vaccines, thousands of cases of illness have been prevented and thousands of lives saved. Finally, for the first time the important bearing of physiology on general medicine has received adequate recognition. "The violences offered to the human body in warfare—whether through exertion and exposure, by terror or excitement, in physical damage by lead or steel, or in chemical attacks on it by poison, and not least through the incredible stresses of flying high and fighting in the air—all these have brought many new and urgent calls for precise physiological knowledge."

The Casualties of the War

The following are the total British casualties of the war, including Dominion and Indian troops. The number killed (including those who died from wounds or other causes) is 658,704. The number wounded is 2,032,142. The number missing, including prisoners, is 359,145. In addition there have been 19,000 deaths from various causes among troops not forming any part of the expeditionary forces. Among the wounded are included those who have been disabled on account of illness.

British Prisoners and German Physicians

The recent report of the government committee, presided over by Mr. Justice Younger, on the treatment of British prisoners of war shows the same abominable cruelty with which we have been familiar since the beginning of the war. Referring to the treatment of the men who were compelled to work in mines, there is this passage: "We come finally to one of the worst points, and at the same time one of the most universal, in the management of the mining camps. The provision made for medical attention in cases of sickness and accident is slight at best, although it might in these instances be considered sufficient if it were properly administered. Each camp is visited once or twice a week by a local civilian physician, who is supposed to be responsible for the medical care of the kommando. He is not called on to treat serious cases, which are passed to the nearest regular hospital. But in all mining work, and more especially in the salt mines, constant vigilance is necessary to prevent even the lighter cases from developing serious consequences. Small accidents are common, the men are in no condition of health to be able to disregard them, and in the salt mines they suffer perpetually from eye trouble and from a distressing kind of abscess, both of which are liable to become dangerously infected in the conditions of their work. In many places the physician is clearly convicted of carelessness and perfunctory treatment." The indignation produced in the medical profession in this country by such disclosures is shown by the decision of the council of the Royal College of Surgeons to omit the universities of Germany and Austria from the list of schools from which certificates of professional education should be received. A similar decision seems about to be taken by the Royal College of Physicians.

PARIS LETTER

Paris, Nov. 28, 1918.

Traumatic Shock

The Société de biologie has been devoting some of its meetings to the discussion of the biology of war. The first meeting of this kind was given over to the study of shock and of anesthesia of wounded men in a state of shock.

Dr. W. B. Cannon of the American army, professor of physiology at Harvard, presented an interesting report on this subject. He said that traumatic shock is a general somatic state, occurring after wounding and characterized by persistent low arterial pressure, accelerated pulse rate, pallor, sweating and rapid superficial respiration. The findings in shock may be summarized as follows: (1) Persistent low arterial pressure. This depression is particularly pathognomonic of shock; in fact, it determines the degree of shock. (2) Hyperglobulia in the capillaries. The difference in the number of erythrocytes to be found in the capillaries and in the veins may be as high as 2,500,000 per cubic millimeter. (3) The body temperature varies with the degree of shock. The blood pressure is low when the victim of shock is cold, but rises as the patient warms up. (4) Reduction of the alkaline reserve in many cases of shock. Often this reduction is sufficiently great to create an acidosis, as defined by Van Slyke. (5) Correlation between the rate of reduction of the alkaline reserve and the degree to which the arterial blood pressure is lowered in an individual who is in the state of shock. (6) Difficulties in the regulation of the circulation. If the blood pressure remains low for a long time, nothing can bring about an elevation in pressure. (7) Marked sensibility of the shock victim to anesthesia with ether or chloroform, affecting the already present low pressure unfavorably. (8) Tolerance for nitrous oxid and oxygen as an anesthetic, without fall of blood pressure.

Dr. Cannon is of the opinion that shock is not due primarily to a loss of vasoconstrictor tonus, nor to fat embolism, but that it is the result of tissue traumatism.

TREATMENT

As far as the treatment of shock is concerned, loss of body heat must be prevented and the normal temperature must be restored. Keep the patient covered; give him hot drinks, apply hot water bottles to the body surface, use plenty of covering, even warm air. Raise the arterial blood pressure as soon as possible so as to avoid the harm which may ensue from lack of oxygen. Blood transfusion may be resorted to because that procedure adds oxygen carriers to the circulation. In cases of trauma to an extremity, apply a tourniquet as close to the wounded area as possible, amputate at once just below it and before taking it off. If the tourniquet applied for the arrest of hemorrhage has to be left in place a long time, it should be applied as near to the periphery as possible. The surgeon must decide whether a limb should be conserved or sacrificed, being guided by the viability of the member, the possibility of losing the isolated portion through gangrene, and the danger to the organism as a whole from the absorption of retention products. If ether is used as an anesthetic to operate on a shock patient, then, as soon as anesthesia is obtained, every effort should be made to raise the blood pressure by transfusion or by injection, repeating these procedures during the operation. Preference should be given to nitrous oxid and oxygen anesthesia, in proportions of three to one, preceded by a hypodermic injection of morphin. Care must be taken to avoid profound anesthesia and cyanosis.

NATURE OF SHOCK

Professor Pierre Delbet stated that this meeting would be historic in that it was the first time that biologists, physiologists, internists and surgeons had met together and agreed almost unanimously on the toxic origin of shock. He considered it fortunate that Dr. Cannon, as a physiologist, and hence free from a surgeon's prejudices, had reached the same conclusions as had been presented by Delbet himself as well as by Dr. Quénu. Apparently the victims of shock are poisoned with toxins which may cause death either by rapid action on the nervous system or by acting on the liver or other organs. These poisons do not combine fixedly with the nerve cells; they are eliminated rapidly, and when fresh doses of toxins do not reach these cells, a rapid cure follows. Irreparable damage to the liver is done only after the lapse of some time. There is a period during which a cure can be effected by preventing a fresh supply of toxin from reaching the nervous system, that is, by eliminating the source of the poison. The exhaustion theory of shock precludes surgical intervention. The rule has been to treat shock patients symptomatically, keeping them warm and giving various injections. The toxic theory of shock, on the other hand, demands surgical treatment, excision or removal of the infectious or toxic focus. Traumatic shock does not contraindicate the operation but calls for it as an emergency measure. However, this does not mean that other means of treatment are useless or ineffective.

Drs. P. Duval and A. Grigaut recalled that the toxic phenomena of primary shock are the direct result of intense and rapid nitrogen disintegration of the traumatized tissues. Under normal conditions the tissues store up a considerable amount of nitrogen products, the result of disassimilation, and it is the retention of these waste products which imparts to them a particular toxicity. Under the influence of trauma, the threshold of nitrogen excretion of that particular cell is lowered, and some of the toxic nitrogen reserve passes out into the circulation.

Dr. C. Vincent limited himself to a discussion of primary traumatic shock, the condition which develops immediately after the wounding, and which is connected either with the wound alone or with certain states which are characteristic of the fighting man and yet are not traumas. In spite of what has been said above, shock is sometimes met with at the regimental first aid posts, hence a careful and thorough examination should be made in every case. The fighting man, especially the infantryman, expends an almost unbelievable amount of energy, which probably paves the way for shock. Experience has shown that after several days of fighting, two thirds of the men in an infantry regiment who are not wounded are in a state of low tension, with a very low blood pressure. Only after four or five days of rest will the pressure go over 12. It is quite likely that many of the men in combat are predisposed to shock, because at the time that they are wounded they are so worn out that they are unable to resist it.

Interallied Conference of Scientific Academies

An interallied conference of scientific academies was held in Paris to consider the question of international scientific relations. Delegates were present from the Royal Society of London, the Edinburgh Academy, the National Academy of Washington, the Accademia dei Lincei of Rome, the Académie royale of Belgium, the Imperial Academy of Tokio, and the Academies of Greece, of Serbia, Portugal, Roumania and Brazil. These delegates met with the French members at the Institut, in the assembly hall of the Académie française.

Influenza Contracted in Military Service

The ministry of war has issued a circular stating that influenza is a contagious disease, hence the widow of a soldier dead of influenza contracted while in service is entitled to a pension.

Return of Prisoners of War

For a long time many prisoners of war, military and civilian, have been returning to Paris from Germany. Many of them are in an unbelievable state of mental and physical depression. It is only too apparent that they have been suffering frightfully from hunger. Some of them seem to have fallen into the lowest depths of misery. Most of them are clothed in rags and are shod with wooden shoes. The civilian prisoners apparently have been subjected to greater privations and hardships than the military prisoners.

The military authorities of Paris have taken measures to expedite the distribution of the military prisoners in various hospital centers where they report for physical examination, which is very important if the spread of contagious diseases is to be avoided. A large number of centres de désinfection have been installed in Paris, especially at the Grand-Palais.

M. Mesureur, directeur de l'Assistance publique, stated that 4,000 of the whole number of beds requisitioned by the military authorities will be held for those soldiers who have or who may contract tuberculosis. There are also 1,200 beds provided in special barracks.

Spanish Medical Mission to Paris

A Spanish medical mission, headed by Professor Martinez Vargas has arrived in Paris. They are to deliver a series of lectures at the Paris medical faculty.

Deaths

Dr. Gustave Bouchardat, professeur agrégé in the Paris medical faculty and honorary professor in the school of pharmacy, is dead, aged 54 years. He has been a member of the Académie de médecine, section of physical and medical chemistry, since 1882. His published works are well known in chemical circles. He specialized on the sugars, caoutchouc and synthetic camphors.

Dr. Paul Puech, adjunct professor of obstetrics in the medical faculty of Montpellier is dead.

Gonorrhea from Military Standpoint

This subject was discussed at the recent meeting of the Congrès d'urologie. Dr. J. Janet of Paris stated that there is no doubt that the number of cases of venereal disease has increased since the beginning of the war, but when the number of soldiers in service is considered, these figures are not so startling after all. At the beginning of the war these diseases occurred more often in the zone des armées than in the interior; the opposite is now the case since the institution of sanitary measures in the former and in the zone des étapes. Gonorrhea among combatant troops can be treated only by means of balsams, the injections being resorted to during rest periods. In the evacuation and base hospitals, the customary treatment is employed. Abortive treatment is successful in two thirds of the cases, provided that it is instituted within twelve hours of the appearance of the discharge. When the treatment is undertaken later than this, success is less apt to be obtained. The urethral lesion is treated by means of injections of potassium permanganate, anterior in cases of anterior urethritis, and throughout the entire urethra if all of the canal is involved, in progressive doses from 0.05 to 0.25 gm. per thousand, depending on the acuity of the inflammation. *In acute cases* two injections should be given every day. The injections should be begun at once, no matter what the degree of acuity of the inflammation (in the anterior urethra alone for a day or two in very acute cases of total urethritis). They should never be discontinued when complications arise for, far from being harmful, the injections have a very favorable influence on their evolution.

Dr. F. Cathelin of Paris discussed the importance of this infection from the military point of view and emphasized the necessity of having a more uniform method of treatment of gonorrhea by means of permanganate in the various centers of treatment. A posterior urethritis can be taken care of better after the war. Vaccine treatment is of most value in treating the complications of gonorrhea, but does not have any effect whatever on the disease itself.

Dr. Pasteau of Paris recommended the organization of a genito-urinary service for the armies. He outlined the method of procedure to be followed by these diagnostic and treatment centers, while the troops are moving as well as while they are resting. The treatment of either simple or complicated gonorrhea at the front should be easy and the results satisfactory.

INDIVIDUAL PROPHYLAXIS

So far as prophylactic treatment is concerned, those interested should be impressed with the fact that the precautionary measures provided, whatever they may be, do not absolutely protect them against all infection, either gonorrhea or syphilis. It is far better, from every point of view, to state distinctly that those who have been exposed to infection have always the risk of contracting infection, and that for their own protection, they should seek treatment at once on the appearance of the very first symptoms. The number of centers of treatment should be increased, their permanency insured and their organization improved if better results are to be obtained than is now the case.

Dr. Keyes of New York spoke of the prophylactic methods employed in the American army, and stated that among more than 60,000 cases there were only 2 per cent. of failures.

TREATMENT IN HOME TERRITORY

Dr. Escat of Marseilles discussed the question of the treatment of gonorrhea in home territory and reported the results obtained in 2,254 cases hospitalized at Marseilles; 1,208 of the men had been treated in the barracks infirmary, 692 at the *Centre de dermatologie-vénéréologie* and 354 at the *Centre d'urologie*. The majority of these 354 cases were of the complicated variety. He was of the opinion that the simple cases, or those cases which are rebellious to treatment without apparent cause, might be treated best in the regimental infirmaries. The French method of treatment, by means of large injections, advocated by Janet, can be applied easily and systematically as an abortive treatment, a rapid or an intensive treatment.

Vaccines have not yielded conclusive results, thus making discussion on this subject impossible. The complicated cases should be treated in the *Centres d'urologie*. From the standpoint of therapeutics as well as discipline, it might be advantageous to put all these cases in an annex to the *Centre*. In the cases with acute glandular complications, after the inflammatory crisis has passed or after early and thorough incision, treatment by large injections is still the method of choice. In the prostatic cases, Escat stated that nonevacuating massage is useless as well as dangerous. In cases of grave epididymitis, epididymotomy is the method of choice; it facilitates the resumption of the lavages or injections. If the complications are chronic, Escat would return to duty all patients who have a chronic urethritis without stricture. All chronic cases, with follicular fistulas or cowperitis, no matter how severe, should not be invalided but operated on and made fit for duty. In all cases of gonorrhea complicated by other lesions, such as phimosis, venereal warts, soft chancre, hard chancre, etc., marked advantage often may be gained from surgical intervention. In cases of stricture, Escat has always succeeded in making lavage and dilating the urethra with the necessary precautions.

Marriages

Henry D. Thomason, Col., M. C., U. S. Army, Commanding General Hospital No. 5, Fort Ontario, N. Y., to Miss Adelina O'Connor, at Fort Ontario, September 25.

Jonas Jay Unger, Lieut., M. C., U. S. Army, to Miss Nettie Avidan, both of New York City, recently.

Charles Foster Campbell, Sunbury, Pa., to Miss Grace High, at Dalmatia, Pa., recently.

Deaths

Josiah A. Powless ⊕ **Lieut., M. C., U. S. Army,** Oneida, Wis.; Milwaukee Medical College, 1904; aged 46; an Oneida Indian, and a graduate of the Indian School at Carlyle, Pa.; who went overseas in the summer of 1918, and was on duty with the so-called "Lost Battalion," of the Three Hundred and Eighth Infantry, Seventy-Seventh Division; died, November 6, as the result of a shrapnel wound of the lung received in battle in the Argonne Forest, October 14.

Edward Cross, Kingsville, Texas; Tulane University, New Orleans, 1862; aged 82; a member of the State Medical Association of Texas; assistant surgeon of the Thirty-First Arkansas Rifles, C. S. A., and later brigade surgeon in the Confederate service during the Civil War; formerly physician to the Arkansas School for the Blind, and professor of gynecology in the University of Arkansas, Little Rock; died at his home, about December 8.

Frederick R. Burnham ⊕ San Diego, Calif.; Detroit Medical College, 1877; aged 65; a member of the staff of the Agnew Sanitarium; a director of the Merchants' National Bank, San Diego; for one term harbor commissioner; president of the board of education; president of the local board of health and a member of the state board of health; died at his home, December 11, from pneumonia.

David Coles Carr, New York City; Bellevue Hospital Medical College, 1868; aged 74; at one time a member of the Medical Society of the State of New York; resident physician at the New York Orthopedic Dispensary from 1868 to 1872, and surgeon to the Harlem Dispensary from 1878 to 1882; hospital steward in the Confederate service during the Civil War; died at his home, December 7.

Michael Philip Schuster ⊕ El Paso, Texas; University of Vienna, Austria, 1889; aged 59; a specialist on diseases of the eye, ear, nose and throat; for many years chief surgeon of the American Smelting and Refining Company, El Paso; president of the El Paso County Medical Society in 1905; founder and president of Providence Hospital, El Paso; died at his home, November 15.

Charles Whitney Haddock, Beverly, Mass.; Harvard Medical School, 1879; aged 62; at one time a member of the Massachusetts Medical Society; a specialist on diseases of the eye, ear, nose and throat; ophthalmic and aural surgeon to the Beverly Hospital; medical examiner (coroner) of the seventh district of Essex County; died at his home, December 13.

Died in the Service
IN FRANCE
LIEUT. JOHN W. RENNER, M. C., U. S. ARMY, 1890-1918

Edward Glenn Henry ⊕ **Lieut., M. C., U. S. Army,** Oil City, Pa.; University of Pennsylvania, Philadelphia, 1911; aged 29; who was on duty at Camp Greenleaf, Chickamauga, Ga., from August to October, when he sailed for overseas; died in American Red Cross Military Hospital No. 4, Mossley Hill, Liverpool, England, November 7, from pneumonia.

Julius H. Jacobson ⊕ Toledo, Ohio; Toledo Medical College, 1897; aged 39; professor of gynecology and clinical surgery in his alma mater; surgeon to the Lucas County and St. Vincent's hospitals; in 1918 president of the Northern Tri-State Medical Association; died in the Hotel Biltmore, New York City, December 11, from pneumonia.

Arthur Monroe Wooster, Rockford, Minn.; Minneapolis College of Physicians and Surgeons, 1911; Hamline University, 1911; aged 31; a member of the Minnesota State Medical Association, and president of the Wright County Medical Society; died at his home, November 23, from pneumonia following influenza.

Jacob F. Wollam, Jerry City, Ohio; Hahnemann Medical College, Chicago, 1893; aged 60; a member of the Ohio State Medical Association; also a druggist; postmaster of Jerry City during the administration of President Harrison; died at his home, December 5, from heart disease.

William M. Tuller, Bowling Green, Ky.; Cincinnati College of Medicine and Surgery, 1876; aged 70; formerly a member of the city council and mayor of Bowling Green; vice president of the Wood County Savings Bank; died at his home, December 4, from cerebral hemorrhage.

Joseph Paul Aster Marin, Holyoke, Mass.; Montreal School of Medicine and Surgery, 1889; aged 57; a member of the board of health of Holyoke, and city physician in 1902; in 1898 to 1899 a member of the board of aldermen; died at his home, December 7, from pneumonia.

George William Wagner ⊕ Detroit; Jefferson Medical College, 1894; aged 54; visiting physician to the Harper Hospital; assistant to the chair of medicine in Detroit Medical College; a specialist in internal medicine; died, December 15, from pneumonia following influenza.

William Edca Williams, Rockledge, Ga.; University of Georgia, Augusta, 1910; aged 33; a member of the Medical Association of Georgia; president of the Laurens County Medical Society; died at Soperton, Ga., October 16, from pneumonia following influenza.

James Page Massie, Sandidges, Va.; University of Virginia, Charlottesville, 1888; New York University, New York City, 1889; aged 52; professor of obstetrics in his alma mater in 1898 and 1899; died at his home, December 7, from pneumonia following influenza.

Cassar Smith, Olean, N. Y.; University of Buffalo, N. Y., 1891; aged 52; at one time a member of the Medical Society of the State of New York; for twenty-one years coroner of Cattaraugus County; died at his home, December 8, from cerebral hemorrhage.

Charles Edward Bradshaw, Columbus, Ohio; Cleveland-Pulte Medical College, Cleveland, 1899; aged 47; for seventeen years a practitioner of Corning, Ohio; at one time a member of the Ohio State Medical Association; died at his home, December 6.

Edward Bradford Reemelin ⊕ Cincinnati; Medical College of Ohio, Cincinnati, 1904; aged 38; formerly assistant professor of physiologic chemistry in the University of Cincinnati; died at his home, December 8, from pneumonia following influenza.

John Walter Renner ⊕ **Lieut., M. C., U. S. Army,** Hilliards, Ohio; Ohio State University, Columbus, 1912; aged 28; who entered the service, July 2, and was soon sent overseas; is reported to have been killed in action, in Flanders, November 4.

George Chrisman Rodgers ⊕ Elkins, W. Va.; University College of Richmond, Va., 1900; aged 46; superintendent and chief surgeon of the City Hospital, Elkins; died at his home, October 25, from pneumonia following influenza.

Dietrich Ludwig Bartling ⊕ **Lieut., M. C., U. S. Army,** Bloomfield, Neb.; Chicago College of Medicine and Surgery, 1917; aged 31; on duty at Fort Sill, Okla.; died at that post, October 20, from pneumonia following influenza.

Henry T. Watkins ⊕ Olney, Ill.; Hahnemann Medical College, Chicago, 1883; aged 58; founder and proprietor of the Olney Hospital; died on a train between Vincennes and Washington, December 4, from heart disease.

Roscoe Howland Healy, Denver, Colo.; Northwestern University Medical School, Chicago, 1918; aged 24; an intern in Barnes Hospital, St. Louis; died in that institution, December 7, from pneumonia following influenza.

Robert H. Eanes, Taylor, Texas; Tulane University, New Orleans, 1883; aged 63; a member of the State Medical Association of Texas; for twelve years a practitioner of Waco, Texas; died in Taylor, December 9.

Jonah S. Miron, Far Rockaway, N. Y.; Fordham University, New York City, 1918; aged 24; superintendent of St. Joseph's Hospital, Far Rockaway; died in that institution, October 20, from lobar pneumonia.

John Busby Ury ⊕ **Capt., M. C., U. S. Army,** Defiance, Ohio; Rush Medical College, 1903; aged 40; died at Fort Oglethorpe, Chickamauga Park, Ga., about December 8, from pneumonia following influenza.

William Hodnett Butler ⊕ Fall River, Mass.; Bellevue Hospital Medical College, 1897; aged 51; a member of the visiting staff of the Fall River Hospital; died at his home, October 11, from influenza.

Henry Nicholas Barth ⊕ Metamora, Ill.; Northwestern University Medical School, Chicago, 1909; aged 33; a specialist in internal medicine; died at his home, November 18, from septic endocarditis.

Harrison C. Hopper, Lawrence, Kan.; Jefferson Medical College, 1879; aged 63; at one time a member of the Kansas Medical Society; died at his home, November 29, from carcinoma of the prostate.

Charles Webster Gould, Jr. ⊕ Atlanta, Ga.; Rush Medical College, 1901; aged 45; formerly a practitioner of Fairdale, Ill.; a specialist in clinical pathology; died at his home, December 1.

John Latham Seay ⊕ Whitwell, Tenn.; Louisville (Ky.) Medical College, 1904; aged 36; died in an infirmary in Birmingham, Ala., November 18, from pneumonia following influenza.

James F. Fitzgibbon, Racine, Wis.; Wisconsin College of Physicians and Surgeons, Milwaukee, 1895; aged 52; died at his home, December 4, from pneumonia following influenza.

Ira Clark Guptill, Northboro, Mass.; Dartmouth Medical School, Hanover, N. H., 1875; aged 74; town physician of Northboro; died at his home, about December 5.

James A. Carson, Maquoketa, Iowa; Hahnemann Medical College, Chicago, 1881; aged 74; a veteran of the Civil War; died in Los Angeles, Calif., December 3.

Albert Charles D'Vorak, Chicago; University of Illinois, Chicago, 1918; aged 32; an intern in Michael Reese Hospital, Chicago; died December 6, from pneumonia.

Charles Henry Shelton, La Jolla, Calif.; New York Homeopathic Medical College, 1880; aged 64; formerly of Montclair, N. J.; died at his home, December 11.

Sverre T. L. Hartman, Vancouver, B. C.; University of Christiania, Norway, 1906; aged 41; died at his home, November 20, from pneumonia following influenza.

James Elwin Snyder, Versailles, Ill.; Chicago College of Medicine and Surgery, 1912; aged 44; died in Cooperstown, Ill., September 17, from carcinoma of the stomach.

August Herman DeFries, Davenport, Iowa; University of Illinois, Chicago, 1896; aged 61; died at his home, November 30, from pneumonia following influenza.

Harvey Wellington Smith ⊕ Carsonville, Mich.; University of Toronto, Ont., 1880; aged 63; died at his home, November 17, from pneumonia following influenza.

Thomas McEwen ⊕ Hemlock, Mich.; Victoria University, Coburg, Ont.; 1886; aged 58; died at his home, about December 4, following a surgical operation.

Elisha Bennett Burnham, Essex, Mass.; Dartmouth Medical School, Hanover, N. H., 1897; aged 47; died at his home, October 10, from bronchopneumonia.

William Turner Parsons ⊕ Palmer, Mass.; Johns Hopkins Medical School, Baltimore, 1907; aged 37; died at his home, November 30, from pneumonia.

William Ellerbe Pelham, Jr. ⊕ Newberry, S. C.; Tulane University, New Orleans, 1905; aged 39; died at his home, October 6, from pneumonia.

Frederick C. Cox ⊕ Newby, Ky.; University of Louisville, Ky., 1904; aged 38; died at his home, October 24, from pneumonia following influenza.

Guy Halifax Wallace, New York City; University of Toronto, Ont., 1909; aged 32; a specialist in pathology; died at his home, December 9.

Joseph Ward ⊕ Cortland, Ohio; Western Reserve University, Cleveland, 1885; aged 59; died at his home, December 4, from nephritis.

Edward Barney Smith, Brightwood, Va.; University of Maryland, Baltimore, 1907; aged 33; died at his home, November 13.

Thomas Allen Smith, Houstonia, Mo.; Hospital College of Medicine, Louisville, Ky., 1881; aged 66; died, recently, at his home.

Eugene Martin, Chicago, University of Illinois, Chicago, 1889; aged 62; died at his home, November 23, from nephritis.

Frank E. Burns, New Orleans; Tulane University, New Orleans, 1891; aged 49; died at his home, November 25.

Correspondence

"THE BIPOLAR BACILLUS OF INFLUENZAL SEPTICEMIA"

To the Editor:—In THE JOURNAL, Nov. 16, 1918, p. 1700, an abstract from *Policlinico,* Rome, describes the cultivation by Ciauri of a bipolar micro-organism in conjunction with gram-positive rods from the blood and sputum of cases of severe influenza. We have recently isolated from a pleural effusion following influenza a bacterium similar in some respects to the bipolar organism described by this author. The following characteristics were noted: The organism was rod shaped, often oval, gram-negative, with distinct bipolar staining and a tendency to variation in morphology. No motility was observed. It grew on plain agar best at 37.5 C., though not heavily, and aerobic conditions were more favorable than anaerobic. Acid was not produced in glucose, lactose or saccharose agar. Gas was not produced in glucose bouillon. Gelatin was not liquefied and litmus milk was not coagulated or rendered acid. Indol production could not be satisfactorily determined because of lack of growth in the peptone medium. A rabbit injected with 1 c.c. of a twenty-four hour bouillon culture intravenously survived. Intraperitoneal injection of smaller doses into a guinea-pig and several mice was not followed by death. This organism apparently falls into the hemorrhagic septicemia group, differing from most of the members of this group by lack of virulence.

EDWARD STEINFIELD, M.D., Philadelphia.

Missouri October Examination

Dr. George H. Jones, secretary of the Missouri State Board of Health, reports the written examination held at Kansas City, Sept. 30-Oct. 2, 1918. The examination covered 14 subjects and included 100 questions. An average of 75 per cent. was required to pass. Of the 24 candidates examined, 21 passed and 3 failed. Fifteen candidates were licensed through reciprocity. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Chicago College of Medicine and Surgery	(1917)	80.3
Loyola University (1916) 81.4;	(1917)	86.1

Book Notices

Walter James Dodd: A Biographical Sketch. By John Macy. Boards. Price, $1.50 net. Pp. 64, with illustrations. Boston: Houghton Mifflin Company, 1918.

Walter James Dodd came to America from England at 10 years of age, and after holding various odd jobs became assistant janitor in the Boylston Chemical Laboratory at Harvard. His chief interest was not in "janitoring," for he followed carefully the work in chemistry with the students regularly enrolled, and was easily able to pass the examinations in the various courses. Later he was appointed assistant apothecary at the Massachusetts General Hospital, continuing his studies in chemistry, and finally passing the state examination and becoming a registered pharmacist. In addition to dispensing prescriptions, the apothecary was official photographer of the hospital, so that Dodd became an expert photographer.

In 1895 were published the first obscure reports of the discovery of the roentgen ray. Mr. Dodd became interested in this work, and was coadjutor in the early work with Dr. Walter B. Cannon on the subject. When Dodd began to work with the roentgen ray, like many other early workers he suffered numerous burns of the hands, and for the next twenty years his hands continued to become more and more crippled and mutilated. It was not learned for several years that the roentgen ray might produce malignant reactions in the tissues. In 1900, Mr. Dodd entered the Harvard Medical School, studying one year, and later continuing his studies at the University of Vermont, where he was graduated in 1908. After his graduation, Dodd was appointed roentgenologist of the Massachusetts General Hospital. In June, 1915, he went to France as roentgenologist with the first Harvard medical unit. Before leaving, it was necessary for him to undergo an operation because of his earlier work with the roentgen ray. He returned to Boston in October, 1915, and seemed to be improving. He lost weight, however, developed enlargement of the glands, and died, Dec. 18, 1916. The laboratory of roentgenology in the Massachusetts General Hospital, it is indicated, will be called the Walter James Dodd Memorial.

The experience of Dr. Dodd is typical of that of most of the early workers in this new field. It is evidence, furthermore, of the way in which men with the true scientific spirit have been wont to surmount great obstacles in their search for scientific advancement, many of them being in every sense of the word martyrs to their professions. The biography of Dr. Dodd is stimulating.

The Medical Record Visiting List or Physician's Diary for 1919. Leather. Sixty Patients per Week. Price, $1.75. New York: William Wood & Co., 1918.

The Physician's Visiting List for 1919. Sixty-Eighth Year of Its Publication. Leather. Price, $1.25. For 25 patients per week. Philadelphia: P. Blakiston's Son & Co., 1919.

These visiting lists conform to the usual style. They are very handy for the keeping of brief records of visits made, engagements for the future and ordinary memoranda. As these books are well known to the profession, it is hardly necessary to do more than state that each is up to its customary standard.

Dental and Oral Radiography. A Textbook for Students and Practitioners of Dentistry. By James David McCoy, D.D.S., Professor of Orthodontia and Radiography, College of Dentistry, University of Southern California. Second edition. Cloth. Price $2.50. St. Louis: C. V. Mosby Company, 1918.

This book deals with the history of roentgenology, including the nature of the roentgen ray and its discovery by Roentgen. The Crookes tube, induction coil, and other apparatus used in producing roentgenograms are described and illustrated. The technic of exposures to secure the best results, with valuable hints on interpretation of dental and oral plates and films, is given. This part of the book is profusely illustrated. The book evidently is intended mainly for the dentist who aspires to become his own roentgenologist, and with this thought in mind the author directs his teaching to the beginner, rather than to the experienced roentgenologist. With this view of the book, it may be recommended without hesitation.

Death from Pricking Pimple an Accident

(Lewis v. Iowa State Traveling Men's Association (U. S.), 248 Fed. R. 602)

The United States District Court, in Iowa, holds that where a man insured by the defendant association died from intentionally pricking a small pimple on his upper lip with a gold scarf pin that he took from his necktie, his lip at the place becoming immediately infected with staphylococcic infection from the scarf pin, which infection spread and caused his death in a few days, it must be considered that he died as the result of bodily injuries received "through external, violent and accidental means," within the terms of his insurance policy. The court says that it may be taken as settled by the great weight of authorities that, under language of this kind in a policy, it is not sufficient that the result shall be accidental, but the "means" must be accidental, as well as the result, which the court thinks was true in this case. If the injury resulted from the pin alone, and there was no proof that the pin was infected, the accidental result would not be covered by the policy; but the insured clearly used something that he did not intend to use. He used not only the pin, but an infected pin—a poisoned pin. This infection was such that it could not, in the nature of things, be discovered by him without perhaps a microscopic investigation. In the court's opinion, the means were clearly accidental. Nor was the defendant exempted from liability under its general convenant to pay, by a provision in its by-laws that the "association shall not be liable . . . for accidental death . . . resulting wholly or partially, directly or indirectly, from . . . local or general infection" (except when such infection or inflammation results from a visible or open wound caused by external, violent and accidental means). The fact that the cocci entered the wound in its making, as agreed by the parties, ought not to make any difference in the construction of this provision of the contract.

Illegal Prescribing of Narcotics

(Commonwealth v. Noble (Mass.), 119 N. E. R. 510)

The Supreme Judicial Court of Massachusetts, which holds that a verdict of guilty returned against the defendant on all the counts must stand, says that the defendant was charged in ninety-six counts in the indictment with unlawfully prescribing narcotic drugs, including morphin, cocain and heroin, when not obviously needed for therapeutic purposes, to persons known to the defendant to be habitual users of such drugs, in violation of Section 2 of Chapter 187 of the Statutes of 1915. The commonwealth offered evidence that any method of treating a drug addict not under the complete control and supervision of the physician, by prescribing narcotic drugs to be administered by the patient, had no justification in the practice of medicine, and that under such a course of treatment the patients were free to go from one physician's office to another and thus secure a supply of such drugs as they desired. There was also evidence that the defendant prescribed morphin and cocain combined, that cocain was prescribed for habitual users of that drug, and that such methods of treatment were improper and without justification; that the doses prescribed were excessive in amount and contrary to the legitimate practice of medicine; that the system followed by the defendant was to prescribe 50 or 60 grains of morphin sulphate to each patient as the initial prescription; and every few days thereafter a similar prescription, calling for a single grain less than the preceding prescription, would be issued to the patient; and that in many prescriptions a quantity of cocain would also be prescribed and reduced in the same manner. Testimony of the defendant, in support of which he offered expert testimony, that the treatment he gave was obviously necessary for therapeutic purposes, was met by the testimony of experts who said that in their opinion such a prolonged reduction treatment was not necessary; that even a sudden withdrawal of the drug was not dangerous, and that they had never known of a case resulting fatally therefrom.

The defendant contended that, being the attending physician in the cases referred to in the indictment, he was the only person who could then determine the obvious necessity for the therapeutic treatment after examination and history of the patient; that his judgment in the matter was conclusive and could not be reviewed or inquired into in a court of law in a trial of an indictment of this kind; and he requested the court so to rule. The presiding judge refused so to rule, and the only question presented for the determination of the supreme judicial court was whether the defendant was entitled to the ruling above referred to, which this court holds that he was not; that the presiding judge rightly refused his request.

The statute provides, in Section 3, for the protection of reputable physicians who act honestly and in good faith. And while the question whether the drug is or is not obviously needed for therapeutic purposes in a given case is a question for the attending physician, and he is not to be held liable for a violation of the statute if he acts in good faith, it does not follow that his judgment in the matter is conclusive and cannot be reviewed or inquired into in a prosecution for an alleged violation of the statute. In the case at bar, on conflicting evidence and the reasonable inferences to be drawn therefrom, it was a question of fact whether the defendant believed the drugs prescribed by him were obviously needed for the treatment of the persons for whom he so prescribed, or whether he was engaged in the business of issuing prescriptions to habitual drug users at $2 each, solely for his pecuniary gain and without reference to the question whether such drugs were obviously needed or not by those who obtained them. The question whether the defendant exercised his honest professional judgment and acted in good faith, or whether he intentionally violated the statute, was a question of fact for the jury, to be determined by them as men of practical sense and sound judgment.

Infirmary Not Liable for Negligence

(Cook v. John N. Norton Memorial Infirmary (Ky.), 202 S. W. R. 874)

The Court of Appeals of Kentucky affirms a judgment in favor of the defendant, which was sued for damages because, through the alleged negligence of the defendant, its nurses, agents and servants, a patient fell from a window and sustained injuries resulting in her death. The court says that an examination of the authorities has convinced it that a purely charitable institution, such as the defendant's hospital was described in the pleadings to be, is not amenable to its patients, although paid ones, for any damages they may have sustained growing out of alleged negligence, although such negligence might consist in the violation by the hospital of some duty imposed by either an express or an implied contract. Some of the cases relieve the defendant of liability on the ground that the doctrine of respondeat superior, or let the master or superior answer, does not apply to purely charitable institutions; but this court has not dealt with that feature of the case, since the conclusion it has reached renders it unnecessary. Neither has this court overlooked the fact that some of the cases relieving the institution of liability impose on it the duty of exercising care in the selection of its servants, which, if it should negligently fail to do, it would be liable. But this court has found it unnecessary to consider that proposition, because there was no allegation presenting that issue. Nor does this court pass on the question of the liability of such institutions for conduct purely tortious, affecting members of the public who are strangers to them. This court would also not be understood as holding that such institutions would not be liable on their contracts made for the purpose of protecting, looking after, and taking care of their physical property, or in supplying themselves with those necessities required for their continued maintenance, since on such contracts they are liable, as are other individuals and corporations.

COMING MEETINGS

Society of American Bacteriologists, Boston, Dec. 30-Jan. 1.

AMERICAN ASSOCIATION FOR THE STUDY AND PREVENTION OF INFANT MORTALITY

Ninth Annual Meeting, held at Chicago, Dec. 5-7, 1918

(Concluded from Page 2102)

The Springs of A Nation's Life

Dr. Edward P. Davis, Philadelphia: To secure a healthy infant population, it is absolutely essential that the conditions of life be such that early marriage can be encouraged. A living wage, sanitary and comfortable means of dwelling, civic sanitation, including a pure and reasonable food supply, and all those agencies which make for physical, mental and moral hygiene are of the utmost importance. No greater curse on the nation in the care of its infant population could be devised than the presence of a large standing army. In continental Europe, marriage is forbidden to men of military age unless they possess a certain stipend. The result has been indiscriminate immorality, and in order to save its population the state is obliged to care for the mothers in hospitals and to rear the children in foundling asylums. The crying need in the prevention of infant mortality is better obstetrics. In order to make improvement in obstetrics possible, the economic and other factors referred to must be present; but without better obstetrics, these factors will be of little value. The encouragement of early marriage in healthy individuals is a step of primary importance; marriage among those physically unfit is to be discouraged, and, if possible, forbidden. It may not yet be possible to require physical examination of men and women before marriage, but the need for such examination is evident.

Education of the laity, nurses and physicians in matters concerning the increase and care of the population is of paramount importance. Why should not a brief, clear statement of symptoms of dangerous conditions arising in pregnant women be posted in rooms used only by women? Why should not the attention of expectant mothers be called to the dangers of miscarriage and convulsions and hemorrhage occurring during pregnancy? Much has been done to educate medical students and physicians for better obstetrics; but economic conditions and lack of hospital facilities have been such that physicians cannot afford to do, in a large private practice, the careful work accomplished in good hospitals. The modern obstetric trained nurse has saved the lives of thousands of infants.

DISCUSSION

Dr. Joseph B. DeLee, Chicago: No matter how much improvement we make in a housing community, social service, etc., unless we are able to teach the public the necessity for better obstetrics and to get most of the people thoroughly acquainted with the needs of the child-bearing woman, we shall fail to produce any remarkable reduction in infant mortality. The prevention of fetal deaths during pregnancy and labor may be summed up in the words "better obstetrics." Grace Meigs' investigation of the U. S. census report shows that child-bearing is as dangerous now as it ever was within our memory, and that the deaths from child-bearing are second in number only to those from tuberculosis.

Conservation of Life of the Unborn and Newly Born Child

Dr. Rudolph W. Holmes, Chicago: It would be desirable that every college for young men and women should have compulsory instruction on the influences of heredity, and give instruction on the general principles of the rights of the unborn. The legislative control of marriages of those afflicted with inheritable disease, requiring a medical certificate from one or both parties, is theoretically correct; in practice it is of questionable value. At present, control of mental defectives is abhorrent to the uneducated mind. Conferences should be held covering the general problem of eugenics; suggestive courses should be given to prospective mothers and to young fathers, that they may meet their responsibilities with intelligence and knowledge. I would have a properly equipped maternity hospital with divisions covering the various needs of the prospective mother and her child before and after its advent into the world. I doubt the expediency of having independent centers.

An ideal center would comprise these divisions: (*a*) There should be a social investigator who should visit the home and determine the true economic need of the family. (*b*) Opportunity and encouragement should be given to all prospective mothers to avail themselves of the antenatal clinics. (*c*) At the time of labor the record of the patient should be transferred, or at least made available, to the maternity department. (*d*) Every woman, before leaving the maternity, should receive positive instructions for her return for a postpartum examination—for recommendations for her own welfare. (*e*) There should be an infant welfare department, including an adequate department for the preparation of foods for infants. (*f*) Systematic courses of lectures should be instituted covering all the phases entering into the questions of personal hygiene, marriage relations, matters cognate to the bearing of children, the care of women in pregnancy, and the care of children thereafter.

The Minnesota Plan for the Establishment of Infant Welfare Clinics in Small Towns

Dr. E. J. Huenekens, Minneapolis: The Division of Child Conservation of the Minnesota State Board of Health has been in existence for six months. In June, 1918, at a meeting attended by all the pediatricians of the state, it was recommended that this division be established and that infant welfare clinics be begun in the smaller communities of the state. Well organized clinics had been in existence for a number of years in Minneapolis, St. Paul and Duluth, so that these places did not have to be considered. It was deemed advisable to establish clinics only where there was a local demand and some kind of local organization that could make the preliminary preparations. This is our method of procedure: When a request for a clinic is received, the head nurse of the division visits the community, explains the object of the work, advises what is necessary in the way of equipment, meeting place, volunteer assistants, etc., and a day is set for the clinic. The advertising of the clinic is left to the local people, and consists of notices in the newspapers, posters, announcements in the churches and schools, and occasionally a house-to-house canvass by block workers. On the day before the clinic, the head nurse again visits the community to make sure that all preparations have been made. In a letter to the local physicians, inviting them to attend the clinic, the director has carefully explained that healthy babies, as well as sick ones, up to the age of 5 years, will be received, though children over that age will not be excluded; advice will be given as to proper diet, especially as to the value of breast feeding, and directions as to clothing and general hygiene; if any pathologic conditions requiring medical or surgical care are found, the patient will be referred back to the family physician for treatment.

Until the next legislature meets, the plans are on a temporary basis, the director being paid per diem, and two full time nurses employed. The budget to be placed before the next legislature, which meets in February, calls for a director on a half time salary and an assistant director on full time salary, three full time nurses and a stenographer and clerk, a total of $15,000 a year. One of our difficulties is to obtain nurses with public health training for these communities. The University of Minnesota and the Minnesota Public Health Association are now cooperating and have established a special four months' course in public health nursing for registered and senior nurses. Until we have sufficient graduates from this course, we intend to have one of our nurses spend several weeks initiating the new community nurse in her duties. The ideal solution for the future would be the establishment in every county, or even smaller units, of full time health officers, trained in infant welfare work, as a part of their public duties.

Rural Work for Infant Welfare in Canada and Other Countries

Dr. Maurice MacDonald Seymour, Regina, Sask.: In the provinces of Canada the effort to reduce infant death rates in the rural districts has consisted of: 1. The establishment at rural points of municipal hospitals subsidized by the government. 2. The appointment of medical men at a salary by municipal councils to serve the rural communities. 3. The conducting of child welfare clinics and exhibits, lectures, etc., at rural centers, more particularly in connection with fairs, when most publicity can be secured. 4. Wide distribution of literature dealing with the care of the baby. 5. The adoption of a system of rural public health nursing, which will be greatly increased in the near future. 6. A government maternity grant to expectant needy mothers in rural districts. 7. Education of the public and wide distribution of literature on the subject of infectious diseases, particularly with regard to the venereal diseases.

In order to improve the situation, the adoption of these measures is to be strongly recommended: 1. A system of dominion-wide training, registration and thorough supervision of midwives. 2. A general system of rural public health nursing, with particular reference to child welfare and prenatal care. 3. The providing of free treatment for all syphilitics by means of cooperation between government and municipal authorities. 4. A more general provision for government aid for maternity cases.

AMERICAN PUBLIC HEALTH ASSOCIATION

Forty-Sixth Annual Meeting, held in Chicago, Dec. 8-11, 1918

(Continued from page 2100)

Organization of Forces Against Influenza

Dr. M. Nicoll, Jr., New York: The general mortality caused by this unknown disease has never been equaled in the country as a whole. This unknown disease kills by secondary pneumonia, usually of a peculiar bronchopneumonic type and due to a variety of organisms, including probably the so-called influenza bacillus. The uncomplicated disease causes a marked leukopenia, together with a profound toxemia, with a tendency toward the production of hemorrhage. The age of special susceptibility is that of young adult life. Among pregnant women it is especially fatal. Those who go to bed and remain there, even with ordinary nursing care, until at least a week after the establishment of full convalescence, will in the large majority of cases recover. Strict quarantine of groups of people has been successful in keeping out the disease.

Dr. William C. Woodward, Boston: The following measures have been adopted for the prevention and spread of influenza: reporting of the disease, the use of masks, the use of vaccines, hospitalization, regulation of the use of common drinking cups in restaurants, lunchrooms, etc.; restriction of crowding; education.

Reporting the disease gives a clue to its prevalence in times of epidemic and serves as a guide in taking measures for the prevention of the disease.

Dr. W. O. Sherman, Pittsburgh: I believe that there is sufficient evidence at hand to warrant us in believing that from a prophylactic standpoint there is some virtue in the use of vaccines in reducing the severity of influenza.

Dr. John Dill Robertson, Chicago: Many places of amusement were closed during the epidemic of influenza to give the people of Chicago more sleep. I believe sleep is the greatest regenerating agent known to mankind. The better class of theaters were not closed, because in them ventilation was good, and such places were used as centers of education for instructing the public regarding the epidemic.

Dr. H. O. Jones, Chicago: The consensus of opinion is in favor of keeping the public schools open during an epidemic of influenza for the following reasons: A better knowledge of existing conditions can be had when the schools are made a source of information as to sickness among the children and their families. It would be possible to supervise the children and keep many of them under better conditions during the school hours than if they were allowed to stay at home and run in streets and alleys, or play on premises where persons sick with the disease lived. We have an organized staff of physicians and nurses for medical inspection of schools.

Dr. Royal S. Copeland, New York: At the peak of the epidemic the death rate in Philadelphia was 140, Baltimore 120, Boston 82, Buffalo 80, Newark 55, and New York 47. For the combined weeks of the epidemic Philadelphia had 55 per 1,000, and New York had 25. So, after all, bad as it was, with 21,000 people dying in our city, it might have been worse.

One Sunday, as I sat in my office, one of the wealthy men of the city and owner of a large department store called me on the phone. He said, "Is this the health commissioner?" I replied, "Yes." He said, "If you do not close the schools and theaters tomorrow you will be indicted." I asked him why I should close the schools and theaters, and he replied, "You must think I am a fool"; and I said, "I am sure you think I am one if you think I should close the schools without good and sufficient reasons." I told him that if we closed the schools it would be equally necessary to close the department stores with their insanitary subbasements, their bargain counters, their overloaded elevators, etc., and the conversation ended. You will be interested to know that after I gave my reasons to this gentleman who differed with me, on last Sunday I dined with him, and he assured me that I was the greatest health officer the world has ever known. As a matter of fact, we did not close the schools and theaters. The very night that this department store man called me up Mr. Hearst called me and said, "This man, who is a large advertiser, wants me to make an attack on you. Will you tell me why you did not close the schools and theaters?" This is what I told Mr. Hearst: The most important part of disease control is the public school system. We have a million schoolchildren in New York, and 700,000 of them come from tenement homes, the poorest homes on earth. It will be better for these children to be permitted to go to school where the schoolhouses are sanitary and are under the strict regulation of the everyday system of disease control than to permit them to linger in the school yards or in the basements, etc. It was better for these children to be attending school than to be at home under unpleasant and unhygienic surroundings. If any child showed symptoms or signs which indicated the possibility of influenza, that child was put in a room by himself until examined by a nurse or by a doctor to discover whether he or she had influenza, and if found to have the disease he was sent home under the care of the board of health, and a board of health doctor or nurse would find out whether the family had a family physician, and if so, whether there was a possibility of isolating and protecting other members of the family. If not, the child was to be placed in a hospital where it could be given care. It is a great deal better to care for children in this way than to turn them loose on the streets to play where they will.

As regards theaters, I never had any doubt about them except the moving picture show. We put a padlock on the unventilated show and used the first-class theaters as places for public health education. Each night some one appeared before the curtain and delivered a short talk to the people, telling them there was no necessity to be frightened, but that coughing and sneezing were the ways by which the disease was transmitted to others, and that they must not cough and sneeze in these places. If they did, they were to be ushered out of the theaters. We made use of these talks to great advantage in promulgating public health education.

A concrete problem in the city of New York is that of the subway. We had conferences with all of the big merchants of New York City and decided to "stagger" hours of travel; that is, we opened and closed places of business according to a certain system, varying the hours of opening in the morning and closing in the evening in different establishments, and this materially reduced the peak of travel in the subway and undoubtedly lessened very materially the number of cases of the disease.

The Rôle of the Hand in the Distribution of Influenza

Col. Charles Lynch and Lieut.-Col. James G. Cumming, Washington, D. C.: The causal organisms of sputum-borne diseases, resident in the mouth and nose, leave the body of the infected through these orifices and enter the noninfected through similar channels. The vehicles for the transfer of germ-laden saliva from and to the mouth and nose are the hands and eating utensils. Crowd diseases have their origin, to a large extent, in the constant accumulative contamination of intermediate objects, which are the distributing centers of the infection for many hands and many mouths. Food may be infected by contaminated hands and then spread the sputum-borne infections, as well as the intestinal-borne infections. In all infectious diseases there are major and minor routes of transmission from the sick to the well. In military life the mess-kit wash water has proved to be the major route, and intermediate object conveyors by hand touch the minor route. Droplet infection is subsidiary to both, because explosive outbreaks do not result from droplet infection, and as far as mouth pathogens are concerned, 18 inches is about the maximum distance that plates on a level with the mouth can be infected by droplets expelled through the act of coughing. Moreover, since the weight of these droplets (even the finest spray) is such that they fall rapidly, the probability of infection by the flight of organisms is remote. It is true that the chain of both direct and indirect transmission may be broken in several ways; one of these is by wearing the mask. This acts in two ways: It prevents droplets from being expelled from the mouth and it also prevents the hands from being put into the mouth. On this basis the value of the face mask may be emphasized. Its value, however, lies in the fact that it serves as a barrier between the hand and the mouth rather than between the mouth and the outside air. The relative importance of this face mask to clean hands is just about the same as in the case of the surgeon who would wear a mask but neglect to wash his hands. In order for the mask to be effective, the wearer must wash his hands before it is removed.

DISCUSSION

Dr. W. H. Kellogg, San Francisco: Gauze masks were given a thorough trial by an ordinance enforcing their use in San Francisco. Beginning with the use of these masks there was a rapid decline in the number of cases of influenza. The experience of Los Angeles has proved that the wearing of masks is a great preventive of the disease. In that city, where they did not use masks, they had a much larger number of cases than in San Francisco. A properly made mask affords efficient protection against droplet-borne infections.

Dr. Woods Hutchinson, New York: The San Francisco people were asked to wear masks in the interest of public health and for public safety. They cooperated with the public health authorities with the result that there was a great reduction in the number of cases of influenza.

Dr. A. J. McLaughlin, Assistant Surgeon-General, U. S. P. H. S., Washington, D. C.: I feel that the question of organization by the federal health forces in this country to meet this great national crisis and to face the situation presented has some extraordinary features. In the first place, if we search the history of this country we shall not find a parallel in the appalling loss of life either in its morbidity or mortality in any epidemic of any kind that has visited the United States. An epidemic of yellow fever with the loss of 1,000 lives spread over considerable territory would throw the whole country into a panic. A dozen cases of plague in a seaport town would cause the same kind of excitement; but it is remarkable to see the placidity with which the people generally have taken the almost sudden loss of 300,000 lives.

In facing the problem of public health, the first consideration is the distribution of the disease, and in considering an epidemic it is very essential to have a trained personnel to assist us in the prevention of the spread of the disease. In this epidemic a remarkable characteristic was that the great majority of availables, medical and nursing personnel, were already in the Army or Navy, so that the available personnel from which to draw was limited. Our next difficulty was the lack of accurate knowledge of the cause and transmission of this disease, and we may as well admit it. There is also a lack of biologic agents with which to prevent the disease, and until we have exact knowledge of the etiology and transmission of the disease we shall not be able by laboratory methods to develop those biologic agencies for prophylaxis, diagnosis and treatment of the disease. We have not acquired sufficient knowledge to know the cause of the disease and then develop in our laboratories some biologic products or agencies that will tell us which man is immune and which is not immune; nor have we an agency that will make people immune or an agent that will cure the disease after a man has become infected. These things are possible only when we get an accurate knowledge of the cause and transmission of the disease.

Our lack of knowledge of the etiology and transmission of the disease makes quarantine measures peculiarly futile. Maritime quarantine is the most exact of quarantine procedures with diseases such as Asiatic cholera. Maritime quarantine is not, as was called in the old days, a sieve but a dam to the entrance of infection. Quarantine against influenza, of which we do not know the cause, makes it possible for carriers to pass any quarantine. Quarantine of the ill is the obvious thing to do. By making the ill individual safe we are quarantining the least active and dangerous of the carriers of the disease. For one ill individual there are hundreds of others not quarantined. We are wearing masks as a protection to individuals. They are worthy of trial.

Many of the measures that have been suggested are not practicable. Restrictive measures, which have been criticised by some, although pretty generally employed by three fourths of the health officers to restrict gatherings of people, are based on sound general principles, and in the absence of any definite knowledge, such as we have of measures against cholera or yellow fever or plague, I would ask you to act on general principles in considering this as a contagious, communicable disease, and educate the people in personal hygiene, to prevent gatherings of people in close contact where greater spread of the infection will occur. We are forced to this by our lack of accurate knowledge. During this epidemic there were sections of the country that were absolutely stripped of physicians, especially in agricultural states, like Nebraska and North and South Dakota, where the small medical population had been taken into the Army. In those states it was necessary to bring in physicians from the outside; but we tried to avoid robbing Peter to pay Paul by organizing federal forces on state lines, so that in every state there was a representative of the United States Public Health Service, either a state health officer acting in that capacity or an officer of the service serving with him in the state capital, to handle relief which the federal government was able to give. With the state health officer and public health officer we had a representative of the American Red Cross appointed for each state. It was necessary to have this kind of organization in order to utilize the limited personnel to the best advantage, because from a central point like Washington it was quite impossible to estimate the relative urgency of calls two or three thousand miles away, whereas the man on the spot knew and could investigate the urgency of these calls and distribute his personnel to the best advantage.

The primary necessity of public health campaigns of this kind is to get accurate knowledge of the prevalence of this disease. Influenza should be a reportable disease, and in epidemic times it is not so essential to depend entirely on physicians. If you establish headquarters or branch headquarters in number according to the population of cities, the calls will come in; and if you have your medical nursing and other relief forces available at headquarters, you will be kept very busy in some places and do a good deal toward preventing the spread of the disease. It is good policy to institute house-to-house inspection and make a canvass for the sick. In the city of Detroit they used 200 schoolhouses when the schools were closed and used the schoolteachers for making house-to-house visits, and in three days these schoolteachers made 2,000 visits in getting information, and reporting to the physicians, which is a very slender reed to lean on when the physicians are so busy and are not getting time to sleep. By this organization of the public health service, while it was largely limited to the extension of sick relief and nursing relief, we were able to do the best that could be done under the circumstances, and at that time the work went along quite smoothly by utilizing the state health officers in cities where we had no representative except the appointment of a field director under the Public Health Service.

Dr. Louis I. Harris, New York: The reorganization of the various health forces of the country for future emergencies and for protecting and caring for recrudescent cases of influenza is very essential. There should be adequate appropriations of money by federal, city and state organizations, so that the work of prevention and treatment can be carried out on a scale commensurate with the importance of the problem.

The Work of the Illinois Influenza Commission

Dr. C. St. Clair Drake, Springfield, Ill.: From the onset of the epidemic, up to and including November 30, reasonably accurate reports from 1,348 Illinois health jurisdictions, within which is embraced 60 per cent. of the total population of the state, show 193,885 reported cases of pneumonia and influenza, 53,000 of which were in Chicago. In the same areas the reported deaths numbered 13,466, of which 9,129 occurred in Chicago.

It was found that no preventive vaccine had been used in twenty-one counties, and that it had been employed only to moderate extent in seventy-two counties. Only four counties in the state claimed its general employment. In addition to the vaccine furnished by the Illinois Influenza Commission and the Chicago Health Department, ten others were used.

As to whether or not these vaccines had served to prevent the spread of infection, nineteen counties offered no definite opinion, twenty-nine answered in the affirmative, twenty-seven were of divided opinion, and sixteen regarded the vaccines as of no preventive value.

Regardless of definite opinions as to the general value of vaccines, based on the experiences of these counties, the following figures were gleaned from these very interesting but highly unreliable questionnaires: counties in which there were no cases after vaccination, 23; counties claiming partial protection, 7; counties in which the severity of the disease was decreased by vaccination, 21; counties claiming prevention of pneumonia but not of influenza by vaccination, 1; counties reporting influenza after vaccination, 24; counties claiming pneumonia after vaccination, 4; counties claiming deaths after vaccination, 4; counties claiming absolutely no preventive value, 4; counties claiming disease increased by vaccination, 2.

Influenza at Great Lakes Naval Training Station

Dr. Owen J. Mink, Great Lakes Naval Training Station, Ill.: When influenza arrived at the Great Lakes Naval Training Station, the incidence increased with explosive violence for about five days. For about four or five days it reached the peak, and for about five or six days more it began to decline, and in two weeks the epidemic began and ended. I have plotted the curves of three of the largest Army camps and they have followed exactly the same curve. These curves indicate that in the average fatal case of influenza the patient lives about seven days before the end. It was very evident that this condition of affairs was not going to occur in civil life. The epidemic explodes in the big military camps, but it does not pursue this course in civil life. The rest of the curve is more gradual; the peak is held slightly longer, and the decline is much more gradual. A cure that covers two weeks in a military camp covers probably two months in civil life. From our figures you can refute almost any theory with regard to influenza that any one wants to advocate. It has been said, for instance, that influenza depends on the number of men in the unit in which the men live. Our camp is composed of units of three in a tent or seventy-five in a barracks, and between these two extremes we have units of twelve who are in contact with no one else outside, that is, men in detention. We have units of twenty-four, sixty, seventy-five, and some units of 150. Taking the several regiments, the largest incidence rate for the epidemic falls roughly between 200 and 300 of 1,000-man regiment, and before the epidemic was over, between 200 and 300 would contract the disease. One tent camp had an incidence of 300 per thousand; one camp composed of seventy-five men (a barracks) had an incidence of a little over 200.

I have no criticism of the mask, as Dr. Weaver intended it probably should be used. My figures are on the mask as it is used. The question came up as to the use of masks among our hospital corps who attended the sick. The medical officer of the regiment handles his own affairs, so that if he was an advocate of the mask he would have the hospital corps men use it. If he did not believe in the mask he did not have the hospital corps men use it. I asked him to keep track of those who used the mask and of those who did not and then to tell me what number of the hospital corps men developed influenza and what number did not. Of the men who used the mask, 8 per cent. developed influenza. Of those who did not use the mask, 7.75 per cent. developed influenza. I should not want to put the blame of the extra 0.25 per cent. on the mask, but the point I wish to bring out is that the mask seemed to have very little influence on the incidence of the disease. Another point of importance in connection with the mask is that long before the influenza epidemic began at the Great Lakes, it became the habit for dentists while operating to put on gauze masks, presumably for the protection of the patient, so that before and during the epidemic our dental officers wore masks, the ordinary influenza mask, and as near as we could determine, and these men had no particular association with the disease, certainly not as much as the hospital corps men, these dental officers developed influenza to the extent of 30 per cent. It is unfortunate that I cannot give you something constructive about the mask, but I believe it is better for you to know these things than not to know them.

Appointment of Committees

Four committees were appointed and presented tentative reports. One committee considered administrative measures; the second administrative measures for relief during the influenza epidemic; the third considered the use of biologic products or vaccines, and the fourth considered the history and statistics of the epidemic.

After a thorough discussion of the papers and reports submitted during the meeting, the following committee was appointed by the association and instructed to prepare a final report for publication as soon as possible as a guide for health officers and physicians generally: Dr. William A. Evans, Chicago, chairman; Dr. D. B. Armstrong, Framingham, Mass.; Dr. W. C. Woodward, Boston; Dr. William H. Davis, Washington, D. C., and Dr. Edward W. Kopf, New York.

Report of the Committee on Administration for Relief During the Influenza Epidemic

Dr. William C. Woodward, Boston: Your committee was charged with the formulation of certain principles for the guidance of health officers in communities for administrative measures and for the relief of epidemic conditions with special reference to influenza. Under general rules the committee suggests compulsory reporting of cases so far as it enables the relief measures to be directed to particular cases that may be reported, and in mentioning compulsory reporting we refer to the matter of isolation and placarding, calling attention to the fact that so far as isolation is compulsory it may lead to a diminished efficiency in reporting, so that while the committee recommends isolation by cooperation and education, it recommends that it be carried to a point where it does not diminish the willingness of the physician to report, and the same principle holds true with respect to placarding. Under preliminary measures the committee recommends the distribution of resources, including physicians, nurses, social workers, nurses' aids, clerks, domestics, laundresses, automobiles, and volunteers of all kinds. The local authorities should keep in touch with state and national agencies.

Report of the Committee on Bacteriology and Vaccines

Dr. William H. Park, New York: Your committee reports that the epidemic disease known as influenza is believed to be due to an undetermined organism which causes an infection that lowers the resistance of the body as a whole and of the respiratory organs in particular. This allows the invasion of other pathogenic organisms. The most important complicating infections are due to influenza bacilli, different strains of pneumococci, different strains of streptococci, etc. In each case one or several micro-organims may be present. In different portions of the country a dominating variety of organism has been found to differ.

Assuming that the cause of the epidemic is an unknown virus, it does not seem possible at present to prevent the primary disease by vaccination with known organisms. Against the secondary infections there would seem to be theoretical basis for the use of vaccines prepared from organisms responsible for the complications that may develop in various localities at various times.

DISCUSSION

Dr. James W. Inches, Detroit: The wearing of masks by the laity on the streets and in public places is of doubtful value. I regard the wearing of masks on the streets as a pure fake. Detroit was closed up for sixteen days during the epidemic. When the theaters and other places were closed in Detroit it deprived the board of health of the opportunity of affording the people education in regard to the epidemic. When everything was wide open the number of cases of influenza was less.

Dr. James A. Hayne, Columbia, S. C.: On receiving a telegram from Surgeon-General Blue regarding the pandemic of influenza, the state health officers of Virginia, North Carolina, South Carolina and Georgia held a conference and issued simultaneously an order for closing, so that every single school, church, theater, moving picture show, etc., was closed, and the closing of these places materially lessened the number of cases of influenza and the death rate. When people assemble in large crowds there is certainly a greater conveyance of droplet infection than if they do not. Eighty per cent. of the population of America is rural, and it is no easy proposition to formulate rules and regulations for the different rural communities. I heartily approve of closing in times of epidemic.

Dr. Roy K. Flanagan, Richmond, Va.: In Richmond, we closed the schools, but what was accomplished by it, I do not know. The results in Richmond compare favorably with other cities in regard to death rate. The death rate was lower in Richmond than in most cities on the Atlantic Seaboard. It was 3.8 per thousand in August and 4.2 per thousand of deaths in the months of September, October and November. There is an epidemic prevailing at present, but the second exacerbation is milder.

Dr. Charles V. Craster, Newark, N. J.: The association should be slow in condeming the use of the gauze mask, because its value has been demonstrated in many instances in preventing bacteria from entering the upper respiratory tract. It is advisable to stop persons from crowding together. Droplet infection is minimized by keeping people apart as much as possible. Rational closing measures should be adopted when epidemic diseases prevail.

Dr. J. O. Cobb, United States Public Health Service, Chicago: Dr. Hayne is right, as there must be rules and regulations for the health officer in the sparsely settled municipalities and communities; but cities like New York, Chicago and Detroit must have some other methods of dealing with the public during a terrible scourge like influenza. The problem must be looked at purely from what one can do and not what might be ideal. One can do in Chicago what he could not do in South Carolina. The prevention of the spread of influenza can be controlled by a properly made and worn mask. The schools should be kept open in all large cities and business allowed to go on as usual.

Dr. Thomas E. Maloney, Fall River, Mass.: Does closing close? Do masks mask? I am prompted to ask this question after the important statement made by Colonel Vaughan that influenza is a hand to mouth disease. So far as I have observed, in many of the rural communities in New England the incidence of the disease is much greater in rural than in industrial communities.

Dr. W. E. Moore, Sioux Falls, S. D.: When the epidemic started in my city we closed up everything for seven weeks, and when we opened wide we had an explosion of the disease, and now we are having more cases than ever. I advise the use of masks for nurses and others who are brought into intimate contact with patients suffering from influenza. An important question is, How long will the disease last? Schools and theaters and other places could not be closed forever.

Dr. J. L. Folkston, S. D.: I agree with Dr. Inches. After the influenza began we secured a supply of the Rosenow vaccine from the Mayo Foundation, and with the free use of this vaccine we have lost only one patient. In regard to the mask, I have told my people not to wear them. I believe that masks are just as filthy a thing as a big, long mustache.

Dr. H. Delamater, St. Joseph, Mo.: The first case of influenza in St. Joseph came from the Great Lakes, September 15. We realized that influenza is a contact disease. We isolated our cases from the start. We do not advocate the use of masks. The mask has been abused and damned by many members. If the mask is condemned for influenza, then why not condemn it in cases of diphtheria, scarlet fever, etc.?

Col. H. S. Cumming, Newport News, Va.: I believe in the value of the mask. It acts as a barrier between the hand and mouth rather than between the mouth and the outside air. Influenza as a crowding disease is a misnomer. When individuals have gathered together in large crowds for the purpose of commercial exchange or theater parties, the incidence of the disease has not markedly increased; but when people have gathered together in large crowds for the purpose of eating, there has generally been an explosive outbreak.

Dr. Frederick Montizambert, Montreal: I believe in the use of the masks for nurses and others who come in contact with the sick. After the mask has been used for a certain time, the circle opposite the mouth becomes moist; and moist surfaces will not receive droplet infection. The droplets will not dry off, and consequently they are sucked into the moist surfaces and protection is not afforded. A dry mask will stop droplet infection. Masks should be frequently changed. Another point in connection with the wearing of the mask is the possibility of infection from the conjunctiva. It is not sufficient to protect the nostrils and mouth, and nurses and others who are stooping over in influenza cases are exposed to droplet infection and should wear masks with transparent eye pieces.

Dr. Milbank Johnson, Los Angeles: I should like to speak of frequent hand shaking in America as a possible factor in conveying the disease. Americans can profit by the custom of the Chinese to shake their own hands as a greeting rather than those of others. If influenza is a contact disease, it makes no difference what kind of a micro-organism is causing the trouble. Doubtless the shaking of hands is a factor in causing its spread and a method of conveying respiratory diseases. I would urge the members to follow the Chinese custom and see if there is anything in it; it does not cost anything.

Treatment of Influenzal Pneumonia with Plasma of Convalescent Patients

Lieut. Frank W. Hartmann, U. S. Navy: To be published in The Journal.

DISCUSSION

Dr. S. R. Pietrowicz, Chicago: My experience has been limited to several hundred cases seen at the Cook County and St. Mary's hospitals, but I believe there is an era of awakening regarding this form of treatment for respiratory diseases. Many physicians still suffer with airophobia and keep their patients in hot rooms, but at the Cook County Hospital the first thing done was to place the patients in rooms with open windows, keeping them well covered, and we found that fresh air is the cornerstone of therapy. Even patients who were cyanotic were greatly benefited almost immediately by this treatment. This has convinced us that fresh air has certain specific properties. First, it is a tonic, then a sedative, a stimulant, and finally an antipyretic. I am sure that its chemical value, its physical value, its respiratory and cutaneous value cannot be overestimated, and this method of treatment should be used more extensively. The contraindications for this treatment are very few—old age, extreme youth, and patients with profuse hemoptysis.

Dr. A. A. Goldsmith, Chicago: I have been under the impression that every man has a different treatment for influenza and pneumonia, and yet has obtained practically the same results, except perhaps at the Great Lakes and other cantonments where the mortality was very high. I thought that certain of the cases were doomed from the start and no treatment, unless perhaps the serum, is of any value. I believe in the fresh air treatment and quiet conditions and think that aside from these one has very little power over the course of the disease. Often patients are continuously stimulated and go on to a fatal termination when, if they had been left alone, many would have recovered. During the last ten years I have tried to leave my patients alone, allowing them to rest as much as possible, giving codein for the cough, if it was necessary, and occasionally morphin, but not bothering about the stimulation. If the toxemia can be combated, that is all that is necessary; and if patients are kept quiet and allowed to sleep, the mortality will be lowered.

Dr. H. N. Bundeson, Chicago: The serum treatment of pneumonia and influenza I believe is of great value, just as like procedures have given similar results in scarlet fever and diphtheria. From the reports of various workers it appears to be almost a specific. The doses should be large, 200 c.c. of convalescent serum given very slowly over half or three quarters of an hour. If there is not a quick drop in the temperature within a short time, another 200 c.c. should be injected. I believe one cause of failure in this treatment is that patients coming from one part of the country are injected with serum from a man from another part of the country, and the serum is probably of a different type. The best results can be obtained from the same type of serum in the same hospital. I believe the serum treatment is efficient only when given early, which is true also of the antidiphtheritic serum.

Lieut. L. R. Melnikoff, Great Lakes Naval Training Station, Ill.: The conclusion at the base hospital at the Great Lakes is that the so-called wonderful cures that have been reported outside of the Army and Navy camps have not been cures of influenzal pneumonia, but of straight influenza or acute cold. On the postmortem table there was no normal tissue left in the lungs in the cases of influenzal pneumonia. The serum treatment has been tried early in the epidemic with very little success, but it is not the same method as that used by Dr. Hartmann. Venesection cannot be successfully done because the circulation in our cases was practically nil and the blood clotted too rapidly. Pneumonia patients did better in the hospital units than those in tents, and most cases were treated in that way. Calomel and salts were given, and in the early cases, some acetylsalicylic acid; but this was soon discontinued, as it was found to be a depressant. If the pulse was over 100, we gave 15 minims of digitalis every three hours. Codein was given in very small doses for the cough and fluid was given frequently, but very little catharsis was employed. Whisky should very seldom be given except as nourishment. Of 3,000 cases at the base hospital, from 20 to 30 per cent. developed pneumonia, and of these about 20 per cent. resulted fatally.

Dr. A. C. Tenney, Chicago: I wish to mention a modification of the vaccine treatment as a preventive measure, thinking that the members may be interested in the results of several years' experimentation and observation, checked by laboratory tests. The idea is simply to furnish an excess of nucleinic acid in the region where the vaccine is introduced. The tissues must be thoroughly massaged after the hypodermics are given. The vaccine selected is introduced in the usual manner, and centrally from that point a dose of nucleinic acid is introduced. I recommend this procedure to those who wish to prevent pneumonia and influenza or a mixed infection from which so many people are suffering. Veratrum viride is not a new remedy. Four years ago it was shown to increase the opsonic index, and this drug in connection with hexamethylenamin has been my mainstay in the treatment of the present epidemic.

Current Medical Literature

AMERICAN

Titles marked with an asterisk (*) are abstracted below.

American Journal of Orthopedic Surgery, Boston

September, 1918, **16**, No. 9

1 Cystic and Fibrocystic Disease of Long Bones. Report of Cases. H. W. Meyerding.—p. 253. (To be continued.)
2 *Practicability of Equalizing Unequal Legs by Operation. F. J. Fassett.—p. 277.
3 Organization of Division of Orthopedic Surgery in U. S. Army with Expeditionary Force. J. E. Goldthwait.—p. 288.
4 *Treatment of Club Foot in Infancy. E. L. Scott.—p. 290.
5 *Rational Treatment of Bone and Joint Tuberculosis. S. A. Twinch.—p. 295.
6 Case of Congenital Deformities of Arms and Legs. C. A. Parker.—p. 302.

2. Equalizing Unequal Legs.—Seven cases are cited by Fassett in which unequal legs were equalized by operative shortening or lengthening. In several instances, three-quarters of an inch was added to the length of a femur, but at a cost of time and hardship too great in comparison with the gain. The bone was divided in a Z-shaped manner—as is done in tendon lengthening. The reason that no more than three quarters of an inch could be gained was not the danger to vessels and nerves, but the fact that these structures are all too well protected by the great strength of the fibrous tissue of the leg. Fassett is of the opinion that if the problem were to be further studied along this line it would seem that the hope of greater gain would lie, not in the application of greater force, but in the clean division of more tendons, fascial bands, or intermuscular planes. Two inches and a quarter and, probably, three inches may be subtracted from the length of a femur without serious loss of muscle tone. This procedure was employed in three cases. If the subtraction method is chosen, the simpler the technic the better. Much was hoped by Fassett from a pattern of osteotomy in which the bone was split first by two longitudinal saw clefts in planes at right angles to each other, and transverse cuts made at two different levels so that four interlocking "fingers" were formed. In the model and in the cadaver, this allows a telescoping movement of the fragments which seems compatible with great firmness. But in the elastic bones of children and young adults Fassett found that this device is not worth the time required to use it in the operation. The operation of choice would appear to be the removal of a simple cylinder of bone of proper length and the fixation of the approximated fragments by a bone splint or Lane plate.

4. Treatment of Club Foot in Infancy.—Assuming an infant with a positive degree of talipes equino varus, the procedure as suggested by Scott would be as follows: At ten days, even much later in most cases, without an anesthetic, the foot is gently manipulated against the resisting structures. Moderate force is used. With the thigh flexed on the abdomen and the leg flexed on the thigh, a tight adhesive plaster strapping is done to the foot, going in the usual way. Shingle straps are applied over the long piece of plaster to insure adhesion. This should correct, to some extent, the inward torsion. The foot is left in this position for about an hour. Then a plaster-of-Paris cast is made of the foot and leg. In the prehardening stage, the thigh is again flexed on the abdomen and the leg on the thigh, the foot is firmly grasped and a forced position, giving as much correction as possible, is taken and held until the plaster is fairly rigid. As soon as expedient, the plaster cast is removed. The original adhesive strapping is removed from the foot, new straps are applied, and the child dismissed for a day.

The plaster model is now corrected by sawing and fitting to conform to the cast of a normal foot. Having corrected the principal elements, equinus and varus, and having overcome the outward bowing of the tibia, the model is shaved off under the outer metatarsals, sandpapered, covered with stockinette, and a cast, of desired thickness, is applied very tightly. By heating and drying, a very strong, light cast is obtained. This is applied to the child's foot and held in place by three straps of adhesive plaster, one at the top, one around the ankle joint, and one across the heads of the metatarsals. These casts can be renewed each ten days. No pressure points or excessive constriction being allowed, the child wears the cast with comfort after a few hours. By measurements of the foot, taken by direction, changes can be made in the model for each cast.

5. **Tuberculin Treatment of Bone and Joint Tuberculosis.**—Twinch records his experiences with the tuberculin treatment of bone and joint tuberculosis. Under modern tuberculin treatment his recoveries have averaged 68 as against 34 per cent. when treated without tuberculin. In addition, the period of treatment of recovered cases averaged only eleven and a half months, while the average time of treatment of recovered cases without tuberculin was five and one-fourth years. Twinch ascribes his good results to the fact that tuberculin acts favorably on the primary focus of infection in these cases. Tuberculin checks the local process, the individual also regaining and maintaining strength not attained by treatment alone on general hygienic and orthopedic lines.

7. **Tumors of Superior Maxilla.**—Fifty-five cases of tumor of the superior maxilla, treated by radium, assisted when necessary by a conservation operation, are analyzed by Janeway. These tumors included eight benign tumors and forty-seven malignant growths, of which four were sarcomas and forty-three epitheliomas. Of the forty-three patients with carcinoma of the superior maxilla a complete retrogression to date has been obtained in eight. Only one of these eight patients has not been traced. Two are within a few months of the three-year period. The other five have passed a little over one year since their treatment was administered. Janeway emphasizes the fact that a percentage of clinical cures to date of 16.2 per cent. in a series containing many advanced and inoperable cases promises a more favorable result by the method used than can be obtained by operation alone.

9. **Surgical Treatment of Diseases by Splenectomy.**—Fourteen splenectomies for disease were performed by Sherren with one death—a boy of 14 on whom the operation was performed for advanced cirrhosis of the liver. The remaining cases were distributed as follows: splenic anemia and Banti's disease, nine; Gaucher's splenomegaly, one; hydatid cyst of spleen, one; splenomegalic jaundice, two.

22 Lavoisier and History of Physiology of Respiration and Metabolism. Contemporary Views of Life Processes. J. C. Hemmeter.—p. 254.

21. **Electromyographic Studies of Clonus.**—A few cases were studied intensively by Cobb by means of the string galvanometer and the results seem to show that clonus gives a typical electromyogram, the details of which, perhaps, throw light on the nature of clonus. Beginning slowly, the periods between contractions soon shorten to a constant length, and this periodicity then varies not at all with fatigue, and only slightly with change of muscular tension. Clonus was kept up for half an hour in one case. In different individuals the average length of these periods varies only by a few hundredths of a second, the shortest being 0.12 second and the longest 0.17 second. The apparatus used for recording the action currents of the muscles studied was the string galvanometer designed by Dr. H. B. Williams. This is a standard machine such as is used in "heart stations" for electrocardiographic work. The optical system and recording camera were also the stock type, except that a special gear was introduced to give greater speed to the film; with this addition a speed of from 20 to 27 cm. per second was obtainable. Five patients were intensively studied; two of these had patellar clonus alone, two had ankle clonus alone, and one had both patellar and ankle clonus.

26. **New Incision for Surgery of Gallbladder and Ducts.**—The incision Usher advocates is the Judd modification of Bevan's incision, except that the peritoneum is cut at an angle of about 45 degrees, or along near the borders of the ribs. The advantages are said to be that the peritoneum is strong in this locality, in fact almost a muscle. Sutures do not tear out readily, as sometimes is the case when the peritoneum is cut straight up and down; there is little likelihood of cutting the diaphragm, an accident that might happen when the peritoneum is cut straight up and down.

35 *Method of Preparing Bacterial Antigens. J. C. Small.—p. 413.
36 Saponin Hemolysis. T. Furuhata.—p. 423.

29. **Complement Fixation Reaction in Tuberculosis.**—Wilson describes a technic which she believes has increased the efficiency of this test. It has to do with the standardization of the guinea-pig's serum to determine the value of the complement. Not all guinea-pigs' serums are efficient for tuberculosis complement fixation. Therefore, the serum from each guinea-pig should be tested for fixability with tuberculosis antigen plus tuberculosis serum before pooling the complement for diagnostic tests. The method of standardizing the complement, the preparation of our tuberculosis antigen, and the diagnostic test, are described in detail.

30. **Complement Fixation Reaction in Tuberculosis.**—Wedel made 1,078 complement fixation tests on 200 specimens of blood serum taken from persons with no clinical history of tuberculosis, and from persons with active, inactive and primary pulmonary tuberculosis. The technic employed was similar to that originally used by Wassermann with slight modifications. The complement fixation results on serums from positive cases made the first day after taking the specimens were negative or weakly positive in a very large percentage of cases; while in most instances, seven days later these same serums gave a strongly positive reaction and continued to give this strongly positive reaction week

after week with unvarying regularity. None of the nontuberculous serums gave a positive reaction the second, third, or fourth week after the specimen had been obtained from the patient. Of all positive serums in the series, only twelve gave a 3 or 4 plus reaction the first day tested. After being preserved in the ice-box under sterile precautions for seven days, forty-nine serums gave 3 or 4 plus reactions. Of eighty-two serums from tuberculous cases of all types that gave negative or doubtful reactions the first day, the results on the seventh day were positive in thirty-seven. The reactions apparently did not change after the sixth day.

Wedel's experiments confirm those reported by Wilson (see Abstract 29) but are in disagreement with all of Corper's conclusions. First, because in Wedel's series of cases there were twenty-six specimens from patients that gave positive Wassermann reactions but offered no physical symptoms of tuberculosis. None of these gave any cross fixation with the Wilson tuberculosis antigen. Second, in no instance did Wedel obtain a positive reaction using double the regular amount of sterile patient's serum in his entire series of known nontuberculous cases. Third, he never found the Wilson antigen to be anticomplementary in four times the dose used in the test, if the antigen is heated at 55 C. for one half-hour just before being used. Fourth, his tests in the active tuberculous cases gave 98 per cent. of positive reactions. Fifth, the very slight turbidity produced by the antigen in no way interferes with the reading of the results. Wedel insists that pooled complement from at least six guinea-pigs should be used in making the tests, or the complement from single pigs should be tested for its complement fixation value with known positive serums. Double the original Wassermann amount of patients' serum should be used. No report should be made until the serum has been tested after having been kept under sterile conditions in the ice chest for from four to six days, preferably six days. Wedel's results seem to indicate that with these modifications of the original complement fixation tests, 100 per cent. of nontuberculous cases will give absolutely negative results; nearly 100 per cent. of the primary and active cases will give positive results, with the exception of the dying persons; and about 25 per cent. of the partially inactive and inactive cases will give only weak positive results.

33. **Preservation of Sheep Corpuscles.**—For the preservation of sheep's erythrocytes, Wenner collects the blood in a sterile bottle containing shot or glass beads, and at once defibrinates it. It is then filtered through sterile cotton into another sterile bottle and the quantity of fibrin-free blood is estimated. This estimation is made readily in a previously graduated bottle; it is often more convenient to determine the quantity by measuring an equal amount of water placed in a similar bottle. One part of 40 per cent. aqueous solution of formaldehyd is added to 800 parts of blood. This formaldehyd-treated blood is kept in the ice box as a stock supply. Whenever erythrocytes are needed, the necessary amount of blood is removed and centrifuged, and the corpuscles washed three times with 0.85 per cent. saline solution.

34. **Skin Reaction to Pneumotoxin.**—The work reported by Weiss and Kolmer is a part of the studies on the properties of pneumotoxin and its probable rôle in the pathology of lobar pneumonia. Guinea-pigs previously sensitized with sublethal doses of pneumotoxin or with the serum or lung exudate of dogs suffering from experimental lobar pneumonia, reacted to the intracutaneous injection of 0.1 c.c. of the toxin by a local erythema and hemorrhagic edema in the subcutaneous tissue overlying the muscle. The skin reaction to heat-killed pneumococci was negative in most of these animals, and when positive, was of a suppurative type, marked by less edema and more leukocytosis. Control animals gave uniformly negative results. Among human adult cases of lobar pneumonia the reaction (which was characteristically that of a local edema and erythema) was elicited as early as the fifth and as late as the thirteenth day of the disease (two days before and six days after the crisis, respectively). In children it was demonstrable about the same time, but was negative immediately or one or two days after the crisis. Patients recovering by lysis reacted as late as the thirty-second day. In general, the test was positive in all active cases, that is, throughout the toxemia. Cases earlier than the fifth day of the disease were not available. Control patients, suffering with bronchopneumonia or with acute or chronic infections not of pneumococcic origin, as well as healthy adults and children did not react. The reaction is regarded by the authors as indicative of a state of allergy to pneumotoxin.

35. **Preparing Bacterial Antigens.**—A chloroform-ether extraction was used by Small to remove the fat-like substances from dried bacteria. After thorough extraction the residue was freed from traces of these solvents and suspended in sterile salt solution. The principles concerned in complement deviation are left behind in this extraction, and the extract contains substances that interfere with the complement-deviation reaction, hence this separation is, in itself, highly desirable. A further advantage is that the chloroform-ether extraction uniformly affects all cells by removing water-insoluble substances and so breaks up the integrity of the individual as to facilitate subsequent aqueous extraction. Complete extraction of the water-soluble fraction cannot be assured since the cellulose fraction left unchanged in the bacterial cell may be so distributed as to impair aqueous extraction. The use of the whole suspensions of this chloroform-ether extracted bacterial residue appears to supply any incompletely extracted bacterial particles to the complement deviation reaction, so that incomplete extraction does not entail a dead loss of the complement deviating substances. To obviate bacterial contamination, which seems to be in some way responsible for a sudden anticomplementary change, the bacterial residue was dried after the last washing with ether, and intimately mixed with eight and one-half times its weight of sodium chlorid. This bacteria-salt mixture was reduced in a mortar to a very fine powder. For use this powder is suspended in distilled water, 0.95 gram per 100 c.c. of water making the right proportions. This is shaken until, on solution of the salt, an evenly distributed, slightly opalescent suspension of the bacteria is effected. Prepared in this manner it yields a 0.1 per cent. suspension of bacteria in normal salt.

45. **Peptic Ulcer and Carcinoma in Duodenum.**—Analysis of a series of 486 patients with duodenal lesions showed that six were cancerous and 480 were benign ulcers, a ratio of one to eighty. In a series of 780 patients with gastric lesions 240 were found to be cancerous and 540 were benign, a ratio of one to two and a fourth. In reviewing his own cases, Lichty found but six cases of carcinoma of the duodenum, and about 240 cases of carcinoma of the stomach, a ratio of one to forty. These diagnoses of gastric carcinoma

were largely verified by necropsy or operation. When neither necropsy nor operation was done, the diagnosis was confirmed by the inevitable course of all cancer cases. Reviewing over 1,000 cases of peptic ulcer, collected during the same period in which the cancer cases were collected, Lichty found a diagnosis of ulcer of the duodenum had been made 480 times, whereas ulcer of the stomach was diagnosed 540 times.

Another interesting observation of this study was the location of the carcinoma in the duodenum. Most reports seem to be of growths which come directly from the pyloric ring or immediately from or about the papilla of Vater. This fact is confirmed very strikingly in the six cases of cancer of the duodenum which Lichty reports. None were found in that area which is most frequently the seat of peptic ulcer. Lichty wonders, if carcinoma of the stomach arises so frequently (50 to 70 per cent., according to some) from a peptic ulcer, why does not carcinoma occur more frequently in the doudenum where peptic ulcer abounds? He throws out the suggestion that the etiologic and determining factor of carcinoma of the stomach may be something entirely independent of peptic ulcer.

46. **Surgery vs. Radium in Cancer of Bladder.**—Barringer maintains that if surgery could cure fifteen cases in 100, radium could cure twenty cases. He reports seven cases, in five of which a cure was effected with radium.

2. **"Spacing Out" as Influenza Preventive Measure.**—Glover urges that when a unit shows a high carrier rate, a distance of at least 2½ feet between the beds should be enforced. This is the "spacing out" referred to in the title.

3. **Subacute Infective Endocarditis.**—The remarkable features about Hudson's case were the insidious and slow progress (eight weeks), the absence of any definite cardiac symptoms, and the fact that the heart never became enlarged, in spite of the severity of the aortic lesion and the long duration of the case. This is attributed to the fact that the large vegetation prevented any real leaking of this valve. The patient was never really "cardiac"; there was no dyspnea or edema, and the pulse maintained a steady, regular, slow beat till the end. He was in a "typhoid" state throughout the disease, and died eventually of a slow toxemia.

4. **Intestinal Obstruction.**—The case reported by Morison and White was an instance of intestinal obstruction due to the healing process of old tuberculous ulcers of the bowel, possibly secondary to a lung infection. Forty years elapsed between the primary attack, and the period during which the patient showed symptoms and was extremely ill.

7. **Peripheral Nerve Injury.**—Burrow and Carter describe in detail their method of examination of nerve injury cases. Their observations after nerve repair point to the following general facts: Trophic and vasomotor functions recover first. Trophic ulcers may heal surprisingly quickly after repair of peripheral nerves. Deep sensibility recovers next, and usually in the order of sense of pressure, perception of movement in joints, etc., and then roughness and pressure pain. Accurate gaging of position and range of movements are slower in their reappearance. Localization of tactile pressure recovers earlier. Radiating, ill-localized sensations, referred to wide areas and usually associated with tingling, appear next; they have a high threshold value, and conform largely to the "protopathic sensation" of Head and Rivers. Next in order come accurate perception of light touch with a gradual disappearance of radiating sensations and a gradual lowering of the threshold value of the stimulus required to obtain responses from the patient. Last of all, and very imperfectly as so far observed, appear the discriminating sensations—that is, stereognostic sense, etc., and lowering of threshold value to those of normal skin. Voluntary movement appears in the highest members of a group of muscles first, and gradually extends downward, as a rule. Motion usually follows the return of "protopathic" sensation. It is present long before the radiating ill-localized sensations are abolished.

10. **Overcoming Adherence of Tendons After Suturing.**—Fenwick cites a case in which he wound thick catgut around each reunited tendon to prevent adherence to the scar and surrounding tissues. The result was excellent.

19 Id. N. T. Brewis.—p. 291.
20 Id. J. H. Ferguson.—p. 294.

12. **Treatment of Splenomegaly.**—A case of splenic anemia is recorded by Eason in which the Wassermann test was positive and antisyphilitic treatment produced definite improvement. The Wassermann test remained positive. The results obtained from specific and surgical treatment are compared by reference to seven collected cases. The late result in one operation case is also noted. The rationale of the surgical treatment is briefly considered. With regard to the management of such cases of syphilitic origin simulating Banti's complex, Eason believes that in the first instance all cases should have very thorough antisyphilitic treatment. No great harm and much improvement may result from this when carried out with care while watching the effect of each injection on the blood. If this has been done, and the Wassermann test still remains positive, operation then becomes almost as necessary as for cases of the orthodox Banti type. The need for operation would not be quite so urgent if from time to time renewed specific treatment were known to rearrest activity. As this prospect is meantime based solely on hypothesis, the indication for operation is practically the same as in Banti's disease, if specific treatment has already failed.

Lancet, London

23 Nephritis in Relation to Recent Epidemic of Influenza. C. P. Symonds.—p. 664.
24 *Tuberculous Disease of Hip-Joint. Sign of Pathological Activity. H. J. Gauvain.—p. 666.
25 *Treatment for Septic Sores and Nile Boils. H. W. Crowe.—p. 667.

22. **War Nephritis.**—The result of Day's inquiry in fifty cases confirms Abercrombie's statement, founded on 500 cases, that the onset of war nephritis was almost invariably attended or preceded by fever. The first symptoms of actual nephritis are an increasing breathlessness and the appearance of edema, generally with more or less cough, headache and pains in the back and legs. Urinary symptoms are only complained of in the special lower tract type. It is impossible to judge of

the severity and outcome of the disease from the nature of the early symptoms. The first sign of approaching recovery is the spontaneous appearance of a diuresis which quickly reduces the edema. This event may occur within a week of the onset in mild cases or be deferred for a month or longer in other patients, while severe cases may reach a tardy convalescence without sudden polyuria. If percussion is employed as well as palpation a definite increase in the size of the spleen can be made out in most cases of trench fever, although it is impossible to feel the organ when it was only moderately enlarged. The use of this combined method, when daily examinations are made, gives most interesting results in trench fever. In all cases where a previous enlargement was excluded the spleen showed alternate advances and recessions at regular intervals of five or six days (rarely four and a half days). This phenomenon occurred in every form of the disease, whether the fever was relapsing or continuous, and in cases where no definite febrile relapse followed the initial bout a second descent of the spleen was evident at the usual interval. The signs of periodicity of this disease evidently are closely related to the accompanying changes in the spleen.

As to complications, bronchitis is very common in the early stages, particularly in patients with considerable edema, or who are suffering from a winter cough—so common in the trenches. As a rule it disappears with the subsidence of edema, but may develop into a septic process with purulent sputum and slight fever. It has been suggested that the relapses seen in war nephritis are due to complications in most cases. Day's experience does not support this view. Other complications, such as uremia, retinitis, cerebral hemorrhages, etc., may occur as in other forms of nephritis. Day believes that the seasonal incidence of war nephritis points to cold and exposure as predisposing agents.

24. **Active Tuberculous Disease of Hip-Joint.**—The most constant and most marked evidence of activity of this disease Gauvain says is spasm of the muscles about the affected joint. As the disease becomes less acute spasm becomes increasingly difficult to demonstrate, until eventually it completely disappears. It may last be elicited in the following manner: If the femur, on the affected side, be grasped firmly in the region of the condyles, the head of the bone may be rotated gently within the acetabulum, either inward or outward, through a varying but often considerable angle. When the disease is active, a further slight sharp rotation is instantly followed by spasmodic muscular contraction, not confined to muscles about the joint but extending to the abdomen and visible in the abdominal muscles, or still more easily demonstrated if the palm of the hand is placed on the abdomen between the iliac spines. Quite a gentle and painless but sharp rotary movement is sufficient to provoke this reflex spasm of the abdominal muscles. In those cases where doubt exists as to the activity of the disease, Gauvain has found it to be a sign of the utmost value. Confirmatory evidence of activity, as indicated by muscular spasm, may at the same time be demonstrated in the following manner: In a child, a finger and thumb of the hand not engaged in grasping the femoral condyles may be applied simultaneously to the two anterior superior iliac spines. During the first rotation of the femur on the affected side no movement is conveyed to the iliac spines. When, however, rotation has been checked and is sharply but gently continued, exaggerated movement in the same direction is transmitted to the iliac spines. With a healthy joint this type of movement is not apparent, with a hip-joint affected with declining but still active tuberculous disease it is very striking, even when the disease otherwise appears to be quiescent.

25. **Septic Sores and Nile Boils.**—A vaccine prepared from a large number of strains of streptococci isolated from septic sores, combined with a similar series of a peculiar staphylococcus isolated from Nile boils, when given in frequent small doses, in conjunction with surgical measures of which the most important is the early incision of boils, Crowe claims to be of great assistance in the cure of these diseases. Increasing the dose of vaccine after cure is complete prevents relapse.

Bulletin de l'Académie de Médecine, Paris

Oct. 29, 1918, **80**, No. 43

26 *The Germans at Lille. A. Calmette.—p. 382.
27 Colloidal Arsenic and Silver in Influenza. M. Capitan.—p. 388.
28 *Artificial Pneumothorax for Gangrene of Lung. P. E. Weill.—p. 393.
29 *Gas Gangrene in 1918. Sieur and R. Mercier.—p. 394.

26. **German Inhumanity at Lille.**—This protest was mentioned in the Paris Letter, page 1929. It is signed by four members of scientific organizations besides Calmette, and specifies a few of the *actes de barbarie* which they witnessed during the occupation of Lille by the enemy. "To list them all," they say, "would fill a volume." The sixty-fourth regimen of Pomeranian infantry, in charge of General Zöllner, during one week last spring selected and deported 10,000 girls and young women from private homes. Almost all the boys from 14 to 18 and the men of 60 to 65 were sent to build dugouts and roads at the front, carry munitions, etc., and the health of many of them has been wrecked, while many died. Leading men and women, to a total of 1,000, were carried off as hostages, Jan. 6 to 12, 1918, the men to Poland, the women to an internment camp in Brunswick. Among the twenty-five who died the first week was Professor Buisine, chief of the chemistry institute. He had heart disease, but the medical major (Dr. Krug) refused to exempt him, saying, "That is not contagious for the German army."

The protest continues: "The high command in Germany willed the war, but the people in arms approved it, and resolutely waged war with the most ferociously cruel means, even the physicians with the army doing the most odious acts without a word of excuse, regret or pity."

28. **Pneumothorax in Treatment of Gangrene of the Lung.**—Weill has found the outcome infinitely better with a gangrenous process in the lung when air is allowed to enter the chest. This causes the lung to retract, and the contents of the gangrenous focus are expelled in a vomica, after which recovery rapidly proceeds. The pneumothorax should be applied under screen control, and be completed and renewed a few days later. In a few cases he injected nitrogen, but usually air sufficed. It is extremely important to detect and thus treat a gangrenous focus of the kind before it has progressed to invade adjoining tissues, as the pneumothorax is impotent against this eventuality.

29. **Gas Gangrene.**—Sieur and Mercier report that the improved methods of rapid evacuation of the wounded and early surgical intervention have brought the cases of gas gangrene down to 0.29 per cent. of the wounded at the advanced posts; 0.19 per cent. in the intermediate zone, and 0.30 per cent. in the interior. Gas gangrene developed in the hospitals of the interior only in 0.068 per cent. of the men who had been operated on before. Aside from the wounded lying too long on the field untended and those with shock too severe to permit operation, it seems that gas gangrene can be avoided, even without specific serotherapy. Among the improvements realized is the recognition that crushing of muscle tissues invites gas gangrene, as also ligation of too many arteries. Surgeons now do not shrink from long incisions and extensive resection of lacerated tissues in such cases. Antigangrene serotherapy has already given encouraging results, and it offers legitimate hopes for prophylaxis.

37 *Electric Treatment of Exophthalmic Goiter. Olivier.—p. 275.

31. **Early Mobilization After War Wounds.**—Kouindjy deplores that joints are still left to grow stiff when the slightest attempt at using the joint might have warded off the ankylosis or the atrophy. In a typical case described, a barbed wire wound of the hand resulted in a felon, and this was given thorough treatment with sunlight and other

measures, but no one heeded that the arm was being carried in a sling unduly long. By the fifth month fibrous ankylosis of the elbow had developed and has proved rebellious to date. Some of the fingers and the wrist are also stiff, and there was considerable atrophy but these have been remedied with time. He has also witnessed cases of ankylosis of the shoulder, after fracture of the radius, and of the ankle after a seton wound of the thigh. On the other hand, he cites some typical instances which demonstrate anew the advantages of early manual mobilization, and how it stimulates consolidation instead of retarding it. Here is a man with merely a felon on one finger, still crippled after five months, while another man with the shaft of the humerus shattered rejoined his company at the front in four and a half months. The shoulder, elbow and wrist were systematically exercised, with traction on the tendon of the biceps, and the different muscles in turn, except the biceps and those of the forearm and hand, were massaged under a jet of hot air. The arm was exercised further with a double pulley and different weights. No mechanotherapy, either active or passive, was applied as this seems to do more harm than good, when there is a tendency to early ankylosis, as in this case.

33. **Albumin in Urine.**—Bauzil determines the proportions of albumin in the urine by comparing the opacity, after addition of trichloracetic acid, with that of some test solutions.

34. **Sugar Solutions for Infusion.**—Duprat and Demolon spare the kidneys the work of passing through them the large molecules of sugar by having the sugar inverted before it is infused. This ensures also its assimilation, as saccharose or any C_{12} sugar is not utilized but is passed into the kidneys in toto. By inverting the sugar, it can be utilized. In one case of grave insufficiency of the liver, 200 gm. of the isotonic sugar solution was entirely utilized. The formula they give for an isotonic "sugar serum" is as follows: Saccharose, 5.4 gm.; distilled water, q. s. to 100 c.c.; normal solution of hydrochloric acid, 6 drops per 100 c.c. The hypertonic "sugar serum" is the same except that the amount of saccharose is doubled. It is sterilized at 100 C. for forty minutes and then at 110 C. for fifteen minutes. He sterilizes at the same time ampules containing 8 drops of a normal solution of sodium bicarbonate to 1 c.c. As the sugar serum is to be used, the contents of an ampule are added to it, thus neutralizing with 1 c.c. of the bicarbonate solution to each 100 c.c. of the sugar serum.

37. **Electric Treatment of Exophthalmic Goiter.**—Olivier reports two cases for which he bespeaks interest on account of the extreme gravity of the cases—death from inanition or heart failure was only a question of weeks—and the intensity of the electric treatment applied. The applications were with 60 volts and 80 milliampères, with large electrodes fitting well to back and neck. One patient took twenty-seven half hour sittings, the other forty-two, daily at first and later with intervals of a week. The women of 26 and 42 were soon restored to clinical health, and the younger has been successfully carrying on a large farm during the husband's absence with his regiment. Olivier tells them to take occasionally a pill containing a little ipecac, digitalis and opium at times of greatest strain.

40 *Immediate Treatment of Spinal Injury. C. Villandre.—p. 561.
41 Indications for Transfusion of Blood in War Surgery. H. Costantini and M. Vigot.—p. 563.

38. **War Nephritis.**—Gouget analyzes his own experiences with 140 cases of nephritis among 7,256 men that passed through his hospital near the front between October, 1914, and March, 1918. Of the total nephritis contingent, seventy-four came from the infantry; seventeen, artillery, and six were hospital orderlies. Among the ninety-three recent cases, a third were evidently secondary to recent typhoid, gonorrhea, syphilis or chilling, and in five cases it had followed after vaccination against typhoid. In fully two-thirds no special cause could be discovered. This is about the same proportion as with nephritis in peace times. There is nothing in the clinical course or ultimate evolution of the cases in which they differ from nephritis under other than war conditions.

40. **Wounds of Spine.**—Villandre protests against the pessimistic views held by many in regard to traumatic injury of the spinal cord. A fracture of a vertebra is often assumed to be a severing of the spinal cord, and it is held impossible to send the man to a specialist center. Fracture of a vertebra impairs but very little the solidity of the spine, so that immobilization is not indispensable. The man should be taken to some point where he can get the collaborating care of a neurologist, surgeon and radiologist. From the very first all medical means should be applied to ward off eschars and urinary infection, and at the earliest possible moment everything liable to press on the cord should be cleared away.

43 *Flatulent Dyspepsia with Exophthalmic Goiter. M. Loeper.—p. 345.
44 Quinin in Prophylaxis of Influenza. R. Tricoire.—p. 347.
45 *Physicians and Poetry. P. Voivenel.—p. 348.

43. **Flatulent Dyspepsia with Hyperthyroidism.**—Loeper states that in four of forty cases of exophthalmic goiter, there was diarrhea and in thirteen cases pronounced dyspepsia. In ten of this latter group there was a tendency to spasm of the esophagus, at different heights. The efforts at swallowing caused much air to be swallowed, and this induced flatulence and meteorism. The air in the stomach may impede its functioning, and there is always a possibility of direct toxic action on the stomach from the disease. Thus both mechanical and toxic factors may cooperate in inducing the type of flatulent dyspepsia in these cases. Improvement is realized by combating the aerophagia and also by operations on the thyroid or other measures to control the hyperthyroidism.

45. **The Nervous Potential.**—Voivenel theorizes that all men are born with an equal *sensibilité, affectivité* or *potentiel nerveux*. It manifests itself in different ways, but, like sap, it has to come up. Charcot, Janet and Freud have shown us the evil consequences of "blocking of the *Affect*." When the excitation, the potential energy does not find a natural outlet, when it cannot be dissipated in the ordinary routine of life, it finds expression in hobbies, in fads of one kind or another. In physicians, it often finds vent in poetry. "The number of practitioners who tickle the muses is legion." . . . "Most of them hide their identity when they do this, but the physician of the day is a philosopher, a *littérateur* or a poet in heart if not in outward manifestation." Voivenel gives a long list of living French confrères who have won recognition as playwrights, novelists or poets. He concludes his list with Prof. Charles Richet who, he says, "washed off anaphylaxis by plunging into poetry, and carried off one of the best academic prizes from under the noses of the professional poets." . . . "These side issues serve as a drain to their nervous potential. It does not go beyond this *menstruation de l'affect*." . . . "One plants roses, another plants cabbages. Which is worth most? It is a matter of opinion. Ask the caterpillars."

46 *Resection of Stomach. H. Iselin.—p. 1425.
47 Organotherapy of Menstrual Disturbances. O. B. Socin.—p. 1431.
48 *Tardy Mercurial Exanthem. M. Umansky.—p. 1435.
49 Clinical Demonstration of the Nerve Fibers in the Retina. J. Strebel.—p. 1442.

46. **Resection of the Stomach for Chronic Ulcers.**—Iselin refers in particular to callous ulcer of the lesser curvature and other ulcers nearer the cardia than the pylorus. He is convinced that only a radical operation will guarantee a permanent cure, while this is the only means to ward off malignant degeneration. He reports transverse resection done in thirteen cases, and while de Quervain applied the Billroth II technic and its modifications, Iselin preferred to restore

the stomach to its approximately normal outline, joining the halves left with a circular suture all around. In his seven cases the technic was entirely successful, and he cites similar experiences from the literature, as also experiences with recurrence of disturbances after mere gastro-enterostomy, and especially malignant degeneration. In eight of Iselin's total twenty-one cases the tumor already showed signs of cancer in the resected piece although, in some, clinically and macroscopically there had been no suspicion of malignant disease. In 1915 he resected the stomach for known cancer in nine cases, and in three the cancer had evidently developed from an ulcer, while an exploratory operation in another presented the same findings. There had been disturbances in these cases from six to twenty-four years. One woman after transverse resection in 1914 died later from cancer of the liver; necropsy revealed a carcinoma at the pylorus although the microscopic findings in the excised ulcer had been those of simple ulcer. It is possible that if the Billroth technic had been followed, this other cancer might have been removed also, so that with known cancer the Billroth II or I might be given the preference. It is possible further that the malignant nature of the excised ulcer might have been recognized if a larger piece had been examined under the microscope.

48. **Tardy Mercurial Eruption.**—Thirty-three days after a vigorous course of mercurial and arsphenamin treatment had been concluded, the man of 33 developed a generalized and severe dermatitis with high fever. By this time there were only traces of mercury in the urine, showing that the eruption could not have been due to cumulative action. Umansky believes that the previous treatment had modified the skin in such a way that an idiosyncrasy developed, although intercurrent functional disturbances of internal organs may have cooperated.

58 *Medical Treatment of Dysenteric Abscess in Liver. T. Pontano.—p. 289.
59 *Clinical Forms of Malaria. A. Borgherini.—p. 308. Conc'n.

50. **Influenza.**—Pontano reports from the medical clinic at Rome, in charge of Ascoli, that the bacteriologic findings were negative both in blood and sputum except for the ordinary germs of the air passages. Inoculation of animals was negative. The influenza bacillus was not found. He thinks that the unknown, probably ultramicroscopic, germ of influenza modifies the lungs in such a way that other germs find ready access to the predisposed soil.

51. **Lethargic Encephalitis.**—The fact that the epidemic of lethargic encephalitis coincided in 1890 with the pandemic of influenza, suggests that it is a localization on the brain of the influenza virus. The disease has appeared anew in the last few months along with pandemic influenza. Both the encephalitis and the influenza commence with a similar onset of catarrhal rhinopharyngitis. Dragotti regards it as identical with the disease known as nona, which was prevalent in Italy at the time of the last pandemic of influenza.

53. **War Wounds of Nerves.**—Fasano concludes from the experiences in the Italian military hospitals that *no time* should be lost in thorough examination of men with painful paralysis. Operative relief should be given at *once*, as this wards off atrophy and ankylosis. When there are no pains, then it is open to discussion whether the gains compensate the disadvantages of operating before the wound is completely healed. During the entire operation, the nerve itself must be continuously flushed with tepid physiologic serum. It must never be left in contact with raw surfaces, but sound muscle or fascia must be drawn around to cover it.

54. **The Bipolar Bacillus of Influenza.**—Ciauri reports the results of further research on the diplomorphous hemoseptic bipolar bacterium which seems to be connected with influenza as described in these columns recently, p. 1700. Among its peculiarities is the long incubation; sometimes five days elapse before the colonies become unmistakable. The *a* form, gram-positive, stains violet with fuchsin, while the *b* form, gram-negative, stains red. These bacteria were cultivated from sputum, blood and urine from the patients and from agar plates breathed on by the patients at 25, or 40 cm. distance. The only animals tested were rabbits, guinea-pigs and fowls. Some of them developed a slow septicemia and the guinea-pigs showed hypothermia, the rabbits slight hyperthermia, but no macroscopic changes in the viscera. The bipolar bacillus proliferates after exposure to dry heat at 80 C. for one hour, and to the freezing point for five hours. The bacillus shows no further development after an hour of moist heat at 100 C. or exposure to 55 C. for five hours. No effect on the bacterium was evident from fifteen and three minutes' contact with 1 per 200,000 or per 100,000 mercuric chlorid solution. These findings although practically negative in the animals tested, yet harmonize with the epidemiology of the disease and suggest means for prophylaxis. The air around the patient contains the germ even in the absence of droplets, and the disease is shown to be septicemia. The practical conclusions are the necessity for free ventilation through the sick room, and redoubled vigilance, with masks, for the physicians and attendants.

55. **Strychnin Activates Malaria.**—Vecchia and Segre have noticed that a malarial attack is liable to follow a dose of strychnin, just as it follows chilling or other cause of abrupt reduction of the defensive forces. They found in Albania that men with old latent malaria had a flare-up attack when given strychnin, and that many of them under quinin then seemed to throw off the disease permanently. In certain others, not suspected of malaria, the strychnin brought on a malarial attack. The strychnin was being given for other reasons, mostly to combat asthenia. It stimulates the tissues throughout, and the malaria bacilli seem to be driven out of the tissues by the strychnin. They are thus exposed more effectually to the action of quinin, so that it seems logical to combine strychnin with quinin in treating old rebellious cases of malaria. Their success in twenty such cases they report as particularly interesting. They say in conclusion that a few large doses of strychnin would decide the question finally whether the malaria was absolutely cured.

56. **Soldering the Wires in Osteosynthesis.**—By this term Egidi means the rebuilding of the shattered bone by fitting all the parts into place and holding them with an encircling wire. The ends of the wire are usually twisted or knotted together, and he here makes a plea to have the ends soldered together instead of twisting them. In all mechanical work, wires are soldered, and nowhere would the advantages be more conspicuous than in the encircling wire of a reassembled bone. To solder a silver wire, he touches the ends where they cross with a pledget barely moistened with zinc chlorid. On this is placed a scrap of tin, and the thermocautery is touched to the tin. It melts at once and the wire is firmly soldered. The projecting ends are cut off; if any sharp point is left this can be buried, too, in a droplet of tin. Or a wedge shaped piece of copper can be heated in the flame and the tip pressed on a block of ammonium chlorid and then on a lump of tin. It melts enough of the tin, which sticks to it, and this is then transferred to the wire to be soldered, already treated with the mordant. There are no twisted ends to compress tissue or break at the weakest point. This soldering of the wire has proved especially useful in cases of fracture of the jaw.

57. **To Transform Street Electric Current for Cystoscope.**—Egidi gives an illustration of a simple home-made device to serve as a rheostat.

58. **Medical Treatment of Dysenteric Abscesses in the Liver.**—The complete failure of surgical measures, in some cases in Macedonia, encouraged Pontano to rely on medical measures alone. His success in some typical cases related has amply demonstrated that with an ameba abscess the

resulting necrosis of liver tissue must be regarded differently from the ordinary pus of a bacterial process. The products of the protozoan process are reabsorbed under the influence of emetin. His cases illustrate the rapid and complete reabsorption of a vast abscess in the liver, even in a case in which there was known associated colon bacillus infection. In this case the liver was reduced from 22 to 12 cm. above the costal arch in twelve days; the leukocytes dropped from 19,000 to 7,500, and repeated examinations of the stools since seem to indicate that the amebic dysentery and the abscess have both been cured. Exploratory puncture in this case had revealed the colon bacillus while encysted amebas were common in the stools. He reiterates in conclusion that "no operation should be attempted for a dysenteric abscess in the liver until a massive course of emetin treatment has been put through."

59. **Clinical Forms of Malaria.**—In concluding this long article Borgherini warns that malaria of a pernicious type, as severe as in the tropics, is encountered now in the near Eastern campaign. The attempt to segregate troops with malaria has failed as the numbers are too large for this.

Rivista di Clinica Pediatrica, Florence

October, 1918, **16**, No. 10

60 *Morbid Associated Movements in Children. P. Busacchi.—p. 505.
61 Growth and Pathology of Twins. A. Borrino.—p. 521. Commenced in No. 9, p. 474.

60. **Synkinesis in Children.**—The case of associated movements described was in a boy of 6 with postdiphtheric paralysis. The muscles of the face and hands were drawn up and distorted with each syllable he tried to speak, even the simplest words. There was no lesion in the cortex, and the synkynesis was bilateral—in both of which points the case differs from others on record, Busacchi remarks. The diphtheric toxin while it paralyzed some of the nerves, seemed to have rendered others more excitable. He describes in detail the probable mechanism of pathologic associated movements in such cases, and reviews the literature.

70 Reflexions on Tuberculosis. J. J. Vitón.—p. 299. Cont'n.
71 Vagotony. A. Austregésilo.—p. 312.

64. **Perforated Chronic Gastric Ulcer.**—The four cases analyzed by Allende presented as the principal element for the diagnosis the sudden intense pain in the epigastrium, usually in the midst of apparent health. Insistent questioning will generally reveal symptoms in the past suggesting possible ulceration. The pulse may keep normal or a little below for the first few hours, which may prove misleading. He advises pouring ether into the peritoneal cavity in concluding the operation, with ample drainage.

66. **Epinephrin and the Frog Heart.**—Flores relates that the heart of the common Argentine frog displays certain physiologic differences from similar animals in Europe and North America. He describes research with epinephrin.

68. **Lingual Goiter.**—Jorge and Layera report in detail two cases of an aberrant thyroid gland at the base of the tongue. Both patients were young women, and the tumor was resected in each. They discuss the literature on the subject, and tabulate the forty-six other cases on record. During the day there is only slight if any interference with breathing, even when the epiglottis is pushed aside by the tumor. But at night, when the muscles of the tongue relax in sleep, there may be episodes of suffocation in certain positions. The tumor may escape detection unless an effort is made to arch the tongue at its base; this throws the tumor into view. The laboratory will exclude syphilis and tuberculosis. With any aberrant goiter, it is necessary to determine whether there is any tendency to thyroid deficit before attempting to remove any or part of the tumor. They regard this as so important that they advise an exploratory incision of the normal thyroid before venturing to remove an aberrant thyroid tumor. Whatever technic is followed for removal of the tumor, tracheotomy seems to be indispensable not only to maintain the respiration but for information in regard to the natural thyroid. Two of the total fifty cases were in infants; there was recurrence after operation in six cases, and postoperative myxedema developed in seven. A colored plate shows the aspect of the lingual thyroid in one case. It contained patches of calcareous degeneration in the one case in which the tumor was removed through an incision. In the other case, it was removed through the mouth under local anesthesia. In two cases the natural thyroid was lacking, and symptoms of myxedema contraindicated any operation.

Oct. 16, 1918, **61**, No. 42

79 *Cartilaginous Exostoses. B. Agerholm.—p. 1425. Commenced in No. 41.
80 *Lipomas as Cause of Ileus. J. Lambrethsen.—p. 1433.

79. **Intermittent Painful and Febrile Cartilaginous Exostoses.**—The case reported by Agerholm is the fourth case on record in which there were recurring attacks of pain, with fever. Nine cases are cited from the records in which the exostoses were painful and tender at times. It is possible that there may be a very mild process of osteomyelitis involved. In Fischer's case, in a boy of 5, each new exostosis as it developed was accompanied by high fever and pains in the bones. In Pels-Leusden's case the first exostosis developed at the age of 28, each new one appearing with fever, pains, loss of appetite and vomiting (unless the patient exaggerated).

80. **Lipomas as Cause of Intermittent Ileus.**—Lambrethsen states that a submucous tumor on a long pedicle obstructed the lumen at the ileocecal junction, causing intermittent ileus in the unmarried woman of 38. In a second case a man of 62 for six years had been having peculiar recurring pains in the abdomen, and vomiting. The intervals were finally only three or four weeks, and the attacks lasted a few hours or days. The symptoms indicated incomplete ileus, and an operation revealed chronic invagination of the upper part of the jejunum entailed by a polypous mucosa tumor. Fully 90 cm. of the bowel were involved in the invagination. He has found records of only fifty-seven similar cases on record, and only thirty-nine were operative cases; the others were casual discoveries. About 50 per cent. were in the large intestine. In a few cases the tumor sloughed off and was eliminated in the stools. In Ninaus' case a stretch, 120 cm. long, was evacuated spontaneously and the patient recovered. The ileus was grave in many cases and from 40 to 50 per cent. succumbed. The prognosis is more favorable when the large intestine alone is involved. In one of his cases there was occult bleeding.

JOURNALS ABSTRACTED IN THE CURRENT MEDICAL LITERATURE DEPARTMENT, JULY-DECEMBER, 1918

The following journals have been abstracted in the Current Literature Department of THE JOURNAL during the past six months. Any of the foreign journals, except those starred, will be lent by THE JOURNAL to subscribers in the United States and to Fellows of the American Medical Association for a period not exceeding three days. Only one journal may be borrowed at a time. Requests for periodicals should be addressed to the Library of the American Medical Association and six cents in stamps should be enclosed. This covers the average expense of mailing a journal. Domestic journals can be obtained by sending the approximate amount direct to the respective publishers. Thus most of the journals indexed are accessible to the general practitioner, no matter where he may be located.

SUBJECT INDEX

This is an index to all the reading matter in The Journal. In the Current Medical Literature Department only the articles which have been abstracted are indexed.

The letters used to explain in which department the matter indexed appears are as follows: "E," Editorial; "C," Correspondence; "T," Therapeutics; "Ml," Medicolegal; "P," Propaganda for Reform; "ME," Medical Economics; "ab," abstract; the star (*) indicates an "Original Article" in The Journal.

This is a subject index and one should, therefore, look for the subject word, with the following exceptions: "Book Notices," "Deaths" and "Society Proceedings" are indexed under these titles at the end of the letters "B," "D" and "S." Matter pertaining to the Association is indexed under "American Medical Association."

The name of the author follows the subject entry in brackets. The figures in parentheses refer to the paragraph in the Current Medical Literature Department, the number following to the page in The Journal.

For author index see page 2217.

A

ABDOMEN, acute inflammation of, diaphragmatic movements in, [Sale] *505
  adhesions, surgical importance of, [Bagley] 1002—ab
  disease, pains with, [Gill] (108) 2114
  drainage of, [Wallau] (116) 1447
  loose bodies in, [Emmert] (107) 1860
  Ptosis of: See Splanchnoptosis
  surgery, transrectus incision in, [Farr] 1001—ab
  traumatic, avoidable, [Deaver] *1120
  walls with gynecologic disease, [Gammeltoft & Wiltrup] (137) 1448
  wounds, gunshot, operation in, [Eastman] *1036
  wounds, gunshot, treated with ichthyol and glycerin, [Duggan] (31) 152
  wounds in war, [Benoni] (61) 779, [Tantoro] (63) 779
  wounds, perforating, [Drummond & Fraser] (25) 1346
ABORTION as sequela of influenza, [Ball] 1336—C
  damages recoverable for, 1433—Ml
  induced, parotitis following, in pernicious vomiting in pregnancy, [Manton] *1041
  passing of curet or conservative treatment of, [Mosher] (62) 1695
  pathologic conditions of pelvic viscera result of induced abortions causing sterilization, [Reder] 1339—ab
ABSCESSES: See also Phlegmon; and under names of organs and regions
ABSCESSES, factitious, early suture for, [Menghetti & Aquilanti] (67) 780
  pelvic, rectal section for, [Ritchie] *424
  retropharyngeal, [Rush] *174
  tuberculous, in thorax, [Tagliavaccho] (99) 781
ACADEMY OF MEDICINE of Paris, donation to, 2011
ACAPNIA and shock, [Henderson & Harvey] (26) 1246
  Henderson's theory of, and nature of surgical shock, [De Almeida & De Almeida] *1710
ACCIDENT, death from pricking pimple on, 2171—Ml
  insurance against sickness and, in Switzerland, [Zanger] (58) 691
  insurance and ophthalmology, [Vogt] (59) 691
  time from and for which after injury medical services may be compensated, 1938—Ml
  what is "accidental" or an accident, 1163—Ml
ACCLIMATIZATION, nature of, [de Langen & Schut] (130) 1447
ACETONEMIA syndrome in children, [Rémond & Poux] (37) 315
ACHONDROPLASIA, [Kummer] (72) 1866
ACHYLIA does not predispose to cancer, [Hofmann] (50) 607
ACID, Acetylsalicylic: See also Aspirin
  acetylsalicylic, acute poisoning by 6 grains of, [Shelby] *1381
  acetylsalicylic, and disposal, 682
ACID, acetylsalicylic, case of aspirin habit, [Macht] (63) 1774
  acetylsalicylic, modifies reaction for sugar, [Kramer] (130) 783
  Amino: See Amino-Acids
  Carbolic: See Phenol
  citric acid content of milk, effect of heat on, [Sommer & Hart] (93) 928
  citric, in milk, 2002—E
  fatty acids and hemolysis, 124—E
  hypochlorous, in chronic arthritis, intravenous injection of, [Fairclough] (10) 313
  Intoxication: See Acidosis
  lactic, as dressing for wounds, [Moruzzi] (57) 608
  lactic, in stomach, significance of, [Rodella] (37) 499, (85) 1444
  margosic, and its salts in syphilis and skin diseases, [Chatterji & Ray] (8) 1093
  phosphoric, distribution of, in normal human blood, [Bloor] (36) 1693
  picric, intoxication and jaundice, 1665—E
  Salicylic: See also Salicylates
  succinic, ferment action on, [Widmark] (141) 784
  trichloracetic, in Vincent's angina, [Gallaher] (60) 600
  uric, and endocrine system, [Silvestri] (61) 608
  uric, endogenous, 124—E
  uric, in blood, new volumetric method for determination of, [Curtman & Lehrman] (46) 1693
  uric, metabolism, endogenous, proteins and amino-acids as factors in stimulation of, [Lewis & others] (33) 1693
  uric, metabolism in asthma and rhinitis, [de Kleyn & Van Leeuwen] (99) 1702
  uric, metabolism, influence of high protein diets on endogenous uric acid elimination, [Lewis & Doisy] (32) 1693
ACIDOSIS, carbon dioxid tension as index of, [Rapin & Turin] (56) 74
  dyspeptic coma with, [Labbé] (43) 1864
  from surgeons' standpoint, [Jeunet] (52) 74
  in diabetes, influence of menstruation on, report of case, [Harrop & Mosenthal] (26) 493
"ACRID PRINCIPLE" of certain plants, 1917—E
ACRIFLAVINE in gonorrhea, [Davis & Harrell] (55) 1694
  secretion of antiseptic urine following intravenous administration of proflavine and, [Davis & White] (57) 1694
ACROMEGALY of larynx, [Jackson] *1787
ACTINOMYCOSIS, intestinal, [Keefe] 1434—ab
ADAMS, Samuel Hopkins, on "Uncle Sam, M.D.," 1064—E
ADDISON'S DISEASE, [Laignel-Lavastine & Porak] (43) 1779
ADENOID tissue of nasopharynx, D. meningitidis in, [Aronson & Friedberg] (56) 2105
ADENOMA sebaceum, 5 cases in 1 family, [Sheimire] *963
ADHESIONS, pericholecystitic, their importance and clinical recognition, [Smithies] *1804
ADIPOSIS DOLOROSA and lipomatosis, [Bourdinière] (66) 1946
  in soldier, [Martelli] (68) 413
ADOLESCENCE, pituitary disturbance and psychoses of, [Tucker] *330
ADRENALIN: See Epinephrin
ADRENALS: See Suprarenals
ADVERTISING and Journal-Lancet, 569—E
  nostrum, in True Blue Bulletin, 1745—E
AEROPHAGIA, [Piedrahita] (99) 936
AEROPLANE surgical unit, [Nemirovsky & Tilmant] (32) 1252
AGED, home for, 2094
AIR, expired, clinical method of collecting, for determination of alveolar carbon dioxid tension, [Roth] (41) 600
  in transmission of epidemics, [Trillat] (54) 2109
  superheated, in surgery, [Iselin] (73) 1866
ALABAMA medical news, 478, 985, 1329, 1422
  state board January examination, 218
  state board July examination, 923
ALBUMIN and blood in stools, [Labbé & Canat] (48) 1698
  examination of sputum for, in pulmonary tuberculosis and chronic bronchitis, [Cornell] (9) 408
  in hemorrhagic cerebrospinal fluid, [Boyer] (40) 932, (66) 1443
  in urine, [Bauzil] (33) 2181
  in urine, new contact test for, [Stewart] *1050
  test for, [Lilliendahl-Petersen] (104) 1100
ALBUMINIMETRY, clinical, for cerebrospinal fluid, [Boyer] (40) 932
ALBUMINURIA, origin of, [Merklen] (50) 1348
  orthostatic, etiology of, [Sonne] (103) 862
ALCOHOL, action of, on muscles, [Gyllenswärd] (142) 236
  benzyl, 1313
  in cerebrospinal fluid, [Lenoble & Daniel] (44) 1864
  Wood: See Methyl Alcohol
ALIMENTARY TRACT: See Gastro-intestinal Tract
ALIMONY, cost of operation added to, 1433—Ml
ALKALI, ammonia excretion as influenced by ingestion of alkalies, [Denis & Minot] (28) 685
  therapy and war nephritis, 1486—E
  therapy of influenza, [Ely & Davidson] 1603—C
ALKALOIDS, comparative value of ipecac and, in intestinal endamediasis, [Simon] *2042
  and malt preparations and retention of calcium in infancy, [Sato] (2) 1692
  test precipitation of, [Sanchez] (84) 1099
ALKAPTONURIA, [Labille] (35) 1011
ALLERGY: See Anaphylaxis; Immunity
ALOES as local sedative, 1991—ab
ALTITUDE, effect of, on ocular functions, [Wilmer & Berens] *1394
  influence of, on hearing and motion-sensing apparatus of ear, [Lewis] *1398

  staining blood parasites and, 2 new French methods for, [Tribondeau] (17) 930
  subcutaneous injection of, [Sicard] (35) 409
  sugar in diabetes, 750—E
  sugar in experimental diabetes, rate of dialysis of, [Kleiner] (55) 224
  sugar in, in tropics, and its importance in acclimatization, [de Langen & Schut] (129) 1447
  sugar in thyroid and other endocrine diseases, [Janney & Isaacson] (36) 1004
  sugar in, test for, [Hagedorn & Jensen] (132) 1354
  transfusion, [Guyot] (45) 316, [Pettavel] (49) 933, [Buchtel] 1245—ab
  transfusion and serum therapy, new methods for, [Hartman] *1658
  transfusion at front area, [Harrison] *1403
  transfusion (citrate method) in hemophilia neonatorum, [Lewisohn] (7) 222
  transfusion, conditions demanding, 1556—ab
  transfusion in field ambulance, [Guiou] (3) 407
  transfusion in meningococcemia, [Ribadeau-Dumas & Brissaud] (45) 2026
  transfusion in surgical patients, 1684—ab
  transfusion in war surgery, [Robertson] (18) 151
  transfusion in war surgery, new modified direct method, [Harrison] (24) 1697
  transfusion of citrated, [Giraud] (26) 315
  transfusion, registry of donors of, 53
  transfusion, value of, in treatment of wounded, [Primrose] (12) 1003
  transfusion with preserved red cells, [Robertson] (2) 407
  urea in human, concentration of, [Kast & Wardell] (6) 2019
  urea in urology, diagnostic and prognostic value of, [Goldstein] *1957
  uric acid in, new volumetric method for determination of, [Curtman & Lehrman] (46) 1693
  vessels, anomalies of bile ducts and, as cause of accidents in biliary surgery, [Eisendrath] *864
  vessels, erosion of, in course of scarlet fever, [Howland] 306—ab
  vessels in neck, war wounds of, [Mocquot] (46) 607
  vessels, injuries from projectiles of war, suture of, [Goodman] (114) 1860
  vessels, multiple vascular anomalies of, in new-born child, [Norris & Miller] (2) 1857
BLOOD vessels, war wounds of, [Okinczyc] (53) 1175
  whole, bactericidal action of, new technic for its determination, [Heist & others] (31) 2021
BLOTTING paper a new dressing for wounds, [Kahn] (69) 1170
BONE and endocrine glands, [Hutinel] (18) 2025
  autografts in bones of forearm, [Losio] (85) 155
  boiled, in operative surgery, [Gallis] (21) 223
  brittle, with blue sclerotics, [Marconi] (81) 319
  cavity, to line with skin, [Thévenard] (57) 1945
  fistulas, persisting, [Bonneau] (65) 1443
  graft, [Imbert] (46) 230, [Charbonnel] (58) 2110
  graft, fractures of tibia following removal of, [Brooke] (24) 223
  graft from monkey, 644—ab
  graft in skull, fate of, [Sicard & others] (45) 1698
  hemorrhagic osteomyelitis and sarcoma in, [Barrie] (5) 1857
  injuries of joint and, at front, treatment of, 1411—ab
  marrow, aplastic, anemia with, [Irisawa & Koga] (108) 414
  marrow, giant cells of, [Jordan] (3) 770
  marrow transplanted into spleen, effect of infection with staphylococci, streptococci and tubercle bacilli on, [Matsuoka] (29) 1346
  marrow, unusual blood cells in diseases originating in, [Thro] (49) 1249
  periosteum grafts, [Virenque] (28) 498
  periosteum in formation of, [Leriche & Policard] (43) 932
  regeneration after resection, 396
  regeneration, hematoma aids in, [Gazzotti] (76) 232
  sensibility of, to pain, [Nyström] (126) 416
  sensibility of, to tuning fork, [Bard] (32) 152
  syphilis, congenital, [Hotz] (66) 232
  tuberculosis, light treatment of, [Berntsen] (126) 158
  tuberculosis of joint and, rational treatment of, [Twinch] (5) 2177
BONE-HOLDING forceps, [Farr] *1554
BONNAIRE, death of, 679
  in memory of Pozzi and, 764
BOOK, device for enabling armless person to turn pages of, [McKenzie] 1683—C
BOTULISM and Heine-Medin disease, [Crookshank] (25) 72
  method of isolating bacillus botulinus from infected materials, [Dickson & Burke] *518
BOWEL: See Intestine
BOWERS' Gallstone Remedy denied use of United States mails, 765—P
BRACHIAL PLEXUS, paralysis of, [van dé Maele] (32) 1615
BRADYCARDIA, clinostatic, [Vincent] (47) 778
BRAILLON, death of, 1760
BRAIN: See also Cerebellum; Pituitary Body; Skull
BRAIN abscess, vaccine for, [Villandre & Rochaix] (36) 152
  changes associated with pernicious anemia, [Woltman] (28) 310

AUTHOR INDEX

In this Index are the names of the authors of articles which have appeared in The Journal, the names of those who have read papers before Societies as published in The Journal and those whose articles have been abstracted in the Current Medical Literature Department. The * preceding the page reference indicates that the article appeared in full in The Journal. The number in parentheses indicates the numbered paragraph on the page referred to. The numbers not in parentheses indicate pages. The author's name is followed by a brief clue to the subject of the article in brackets.
